Neck ultrasonography should be performed to measure the size of a nodule and to determine whether a palpable nodule is part of a multinodular goiter. The following ultrasound characteristics of thyroid nodules increase the likelihood of malignancy: irregular or indistinct margins, heterogenous nodule echogenicity, intranodular vascular images, microcalcifications, complex cyst, or diameter over 1 cm. Ultrasound is also useful for long-term surveillance of thyroid nodules and multinodular goiter. Ultrasonography is generally preferred over CT and MRI because of its accuracy, ease of use, and lower cost.

RAI (^{123}I or ^{131}I) scans have limited usefulness in the evaluation of thyroid nodules. Hypofunctioning (cold) nodules have a somewhat increased risk of being malignant but most are benign. Hyperfunctioning (hot) nodules are ordinarily benign but may sometimes be malignant. RAI uptake and scanning is helpful if a patient is found to have evidence of hyperthyroidism. (See Hyperthyroidism, above.)

CT scanning is helpful for larger thyroid nodules and multinodular goiter; it can determine the degree of tracheal compression and the degree of extension into the mediastinum.

Incidentally Discovered Thyroid Nodules

Thyroid nodules are frequently discovered as an incidental finding, with an incidence that depends on the imaging modality: MRI, 50%; CT, 13%; and [^{18}F]fluorodeoxyglucose positron emission tomogrpahy (18FDG-PET), 2%. When such scanning detects a thyroid nodule, an ultrasound is performed to better determine the nodule's risk for malignancy and the need for FNA biopsy (see above), and to establish a baseline for ultrasound follow-up. The malignancy risk is about 17% for nodules discovered incidentally on CT or MRI, and 25–50% for nodules discovered incidentally by 18FDG-PET. For incidentally discovered thyroid nodules of borderline concern, follow-up thyroid ultrasound in 3–6 months may be helpful; growing lesions may be biopsied or resected.

Fine-Needle Aspiration Biopsy

FNA biopsy is the best method to assess a thyroid nodule for malignancy. FNA biopsy can be done while patients continue taking anticoagulants or aspirin. For multinodular goiters, the four largest nodules (1 cm diameter) should be biopsied to minimize the risk of missing a malignancy. Smaller thyroid nodules (8–10 mm) with a suspicious appearance on ultrasound should also be considered for ultrasound-guided FNA biopsy. Using ultrasound guidance for FNA biopsy improves the diagnostic accuracy for both palpable and nonpalpable thyroid nodules. The chance of an optimal tissue sampling is also improved by having an experienced clinician perform the FNA biopsy and by having the aspirate interpreted by a skilled cytopathologist.

In one review of thyroid FNA biopsies, about 70% were benign, 5% were malignant, 15% were nondiagnostic, and 10% were indeterminate or "suspicious."

When FNA cytology is "suspicious" for papillary thyroid carcinoma, the risk of malignancy is 57%. When FNA cytology yields a "suspicious" follicular lesion, the overall risk of the lesion being malignant is about 20–25%. However, the risk is lower in patients aged 50 years. The risk that a follicular lesion is malignant increases for patients who are much younger or older than age 50. Most patients with suspicious FNA cytology undergo thyroid surgery.

Cystic nodules yielding serous fluid are usually benign, but fluid should be submitted for cytologic testing. Cystic nodules yielding bloody fluid have a higher chance of being malignant. Repeat FNA biopsy is done with ultrasound guidance if the cytologic test results are nondiagnostic (eg, diluted with blood or hypocellular) and the lesion remains palpable.

False-positive thyroid FNA biopsy results occur at a rate of about 4%. False-negative thyroid FNA biopsy results also occur at an overall rate of about 4%, less commonly when performed under ultrasound guidance and interpreted by cytopathologists. False-negative results delay surgical excision and lead to an increased risk of vascular and capsular invasion by the malignancy. Some false-negative FNA biopsy results may not have actually been inaccurate, since truly benign thyroid nodules can later become malignant. Patients who have a negative thyroid FNA should have observational follow-up, ideally with both palpation and ultrasound; nodules that continue to grow should be rebiopsied or excised.

Treatment

All thyroid nodules, including those that are benign, need to be monitored by regular periodic palpation and ultrasound and rebiopsied if growth occurs. A toxic multinodular goiter and hyperthyroidism, associated with the ingestion or intravenous administration of large amounts of iodine, may develop in patients with multinodular goiters. It is therefore prudent to minimize excessive dietary iodine intake and intravenous iodinated contrast. Patients found to have hyperthyroidism may have a RAI uptake and scan for additional evaluation, especially if ^{131}I is a therapeutic consideration. Patients with toxic multinodular goiters may also be treated with methimazole, propranolol, or surgery (see Hyperthyroidism section).

Levothyroxine Suppression Therapy

Patients with elevated levels of serum TSH are treated with levothyroxine replacement. Otherwise, for small benign thyroid nodules, levothyroxine suppression therapy is not required. For larger nodules (> 2 cm), if TSH levels are elevated or normal, "suppression" with levothyroxine (starting doses of 50 mcg daily) can be considered. Levothyroxine should not be administered if the baseline TSH is low, since that is an indication of autonomous thyroid secretion, such that levothyroxine therapy will be ineffective and liable to cause clinical thyrotoxicosis. Long-term levothyroxine suppression of TSH tends to keep nodules from enlarging, but only a few will actually shrink. In one 5-year study, thyroid nodule size increased in 29% of patients treated with levothyroxine, compared to growth in 56% of nodules in patients not receiving levothyroxine. Levothyroxine suppresssion also reduces the emergency of new nodules: 8% with levothyroxine and 29% without levothyroxine.

Levothyroxine suppression needs to be carefully monitored, since it carries a 17% risk of inducing symptoms of hyperthyroidism. This can occur due to excessive levothyroxine dosing, the emergence of an autonomous or toxic nodule or Graves disease, or a reduction in thyroid binding globulin seen in early menopause or with discontinuing oral estrogen therapy. Therefore, levothyroxine suppression therapy is most suitable for younger patients. All patients require regular careful clinical evaluation and thyroid palpation or ultrasound examinations. Levothyroxine suppression therapy is not usually given to patients with cardiac disease, since it increases the risk for angina and atrial fibrillation. Levothyroxine suppression causes a small loss of bone density, particularly in postmenopausal women. Patients at risk for osteoporosis are advised to have periodic bone density testing. Bisphosphonate or other therapy for osteoporosis may be indicated.

Surgery

Total thyroidectomy is required for thyroid nodules that are malignant on FNA biopsy (see Thyroid Cancer section). More limited thyroid surgery is indicated for benign nodules with indeterminate or suspicious cytologic test results, compression symptoms, discomfort, or cosmetic embarrassment. Surgery may also be used to remove hyperfunctioning "hot" thyroid adenomas or toxic multinodular goiter causing hyperthyroidism (see Hyperthyroidism section).

Ethanol Injection

Percutaneous ethanol injection has been used to shrink benign (biopsy proven) thyroid nodules, both solid and cystic. Most nodules undergo partial shrinkage after percutaneous ethanol injection. The complication rate is about 9%, although serious or permanent complications are rare.

Radioiodine (^{131}I) Therapy

Radioactive ^{131}I is a treatment option for hyperthyroid patients with toxic thyroid adenomas, multinodular goiter, or Graves disease (see Hyperthyroidism section). It may also be used to shrink benign nontoxic thyroid nodules. Thyroid nodules shrink an average of 40% by 1 year and 59% by 2 years after ^{131}I therapy. Nodules that shrink after ^{131}I therapy generally remain palpable and become firmer; they may develop unusual cytologic characteristics on FNA biopsy. Hypothyroidism is a risk and may occur years after ^{131}I therapy, so thyroid function testing must be performed regularly.

Prognosis

The great majority of thyroid nodules are benign. Benign thyroid nodules may involute but usually persist or grow slowly. About 90% of thyroid nodules will increase their volume by 15% over 5 years; cystic nodules are less likely to grow. Cytologically benign nodules that grow are unlikely to be malignant; in one series, only 1 of 78 rebiopsied nodules was found to be malignant. The prognosis for patients with thyroid nodules that prove to be malignant is determined by the histologic type and other factors (see below). Multinodular goiters tend to persist or grow slowly, even in iodine-deficient areas where iodine repletion usually does not shrink established goiters. Patients with very small, incidentally discovered, nonpalpable thyroid nodules do require follow-up with thyroid ultrasound but are at low risk for malignancy. Nodules that are malignant have a minor effect on morbidity and mortality.

Thyroid Cancer

Essentials of Diagnosis

- Painless swelling in region of thyroid.
- Thyroid function tests usually normal.
- Past history of irradiation to head and neck region may be present.
- Positive thyroid needle aspiration.

General Considerations

The incidence of papillary and follicular (differentiated) thyroid carcinomas increases with age. The overall female:male ratio is 3:1. The yearly incidence of thyroid cancer has been increasing in the United States, with the number of cases diagnosed annually reaching 33,500, probably as a result of the wider use of CT, MRI, PET, and ultrasound that incidentally find small thyroid malignancies. Thyroid cancer mortality has been stable, accounting for about 1500 deaths in the United States annually. At autopsy, microscopic thyroid cancer is found with surprising frequency. Clearly, most thyroid cancers remain microscopic and indolent. However, larger thyroid cancers (palpable or 1 cm in diameter) are more malignant and require treatment.

Papillary thyroid carcinoma is the most common thyroid malignancy (Table 26–7). Pure papillary and mixed papillary-follicular carcinoma represent about 80% of all thyroid cancers. It usually presents as a single thyroid nodule, but it can arise out of a multinodular goiter. Papillary thyroid carcinoma is commonly multifocal within the gland, with other foci usually arising de novo rather than representing intraglandular metastases. About 10% of cases present with palpable cervical lymph node metastases from a small thyroid cancer. Papillary thyroid carcinomas tend to grow slowly and often remain confined to the thyroid and regional lymph nodes for years. However, they may become more aggressive, especially in patients over age 45 years, and most particularly in the elderly. The cancer may invade the trachea and local muscles and may spread to the lungs.

Table 26–7. Some characteristics of thyroid cancer.

	Papillary	**Follicular**	**Medullary**	**Undifferentiated**
Incidence	Most common	Common	Uncommon	Uncommon
Average age	42	50	50	57
Females	70%	72%	56%	56%
Invasion				
Juxtanodal	+++++	+	++++++	+++
Blood vessels	+	+++	+++	+++++
Distant sites	+	+++	++	++++
^{123}I uptake	+	++++	0	0
Mortality	+	++ to +++	+ to ++++	++++++++

Papillary thyroid carcinoma is caused by certain genetic mutations or translocations. Activating mutations of the *ras* oncogene can cause benign thyroid adenomas or nodular goiter. Additional activating mutations in *BRAF* or *TRK* genes can lead to papillary carcinoma. About 45% of papillary thyroid carcinomas are caused by over expression of the *ret* oncogene by the translocation of certain gene promoters to it, producing *retPTC-1*, *retPTC-2*, or *retPTC-3*. Radiation treatments to the head and neck region tend to cause *retPTC-1*. Nuclear fallout exposure tends to cause *retPTC-3*, resulting in more aggressive papillary thyroid carcinomas. Additional loss of the *p53* tumor suppressor gene can cause progression of papillary thyroid carcinoma to anaplastic thyroid carcinoma.

Exposure to radiation therapy to the head and neck poses a particular threat to children who then have an increased lifetime risk of developing thyroid pathology, including papillary thyroid carcinoma; thyroid malignancy may emerge between 10 and 40 years after exposure, with a peak occurrence 20–25 years later. After an explosion at the Chernobyl Nuclear Plant in the Ukraine in 1986, the risk of developing papillary thyroid carcinoma was highest among children who were under age 5 at the time of exposure to radiation; emergence of more aggressive papillary thyroid carcinoma occurred within 6–7 years after exposure.

Papillary thyroid carcinoma can occur in familial syndromes as an autosomal dominant trait, caused by loss of various tumor suppressor genes. Such syndromes (with associated features) include familial papillary carcinoma (with papillary renal carcinoma); familial nonmedullary thyroid carcinoma; familial polyposis (with large intestine polyps and gastrointestinal tumors); Gardner syndrome (with small and large intestine polyps, fibromas, lipomas, osteomas); and Turcot syndrome (with large intestine polyps and brain tumors). Older patients with multinodular goiter may rarely develop a papillary thyroid carcinoma. Papillary carcinoma can sometimes undergo a late anaplastic transformation into an aggressive carcinoma.

Generally speaking, papillary carcinoma is the least aggressive thyroid malignancy. However, the tumor spreads via lymphatics within the thyroid, appearing to be multifocal in 60% of patients and involving both lobes in 30% of patients. About 80% of patients have microscopic metastases to cervical lymph nodes. Unlike other forms of cancer, patients with papillary thyroid carcinoma who have palpable lymph node metastases do not have a particularly increased mortality rate; however, their risk of local recurrence is increased.

Occult metastases to the lung occur in 10–15% of differentiated thyroid cancer. About 70% of small lung metastases resolve following ^{131}I therapy; however, larger pulmonary metastases have only a 10% remission rate.

Microscopic "micropapillary" carcinoma (1 mm and invisible even on thyroid ultrasound) is a variant of normal, being found in 24% of thyroidectomies performed for benign thyroid disease when 2-mm sections were carefully examined. It thus appears that the overwhelming majority of these microscopic foci never become clinically significant. The surgical pathology report of such a tiny papillary carcinoma that is otherwise benign does not justify aggressive follow-up or treatment because a cancer diagnosis is unwarranted and harmful. All that may be required is yearly follow-up with palpation of the neck and mild TSH suppression by thyroxine.

Follicular thyroid carcinoma and its variants (eg, Hürthle cell carcinoma) account for about 14% of thyroid malignancies; follicular thyroid carcinoma is generally more aggressive than papillary carcinoma. Rarely, some follicular carcinomas secrete enough T_4 to cause thyrotoxicosis if the tumor load becomes significant. Metastases commonly are found in neck nodes, bones, and lungs. Most follicular thyroid carcinomas avidly absorb iodine, making possible diagnostic scanning and treatment with ^{131}I after total thyroidectomy. Certain follicular histopathologic features are associated with a high risk of metastasis and recurrence: poorly differentiated and Hürthle cell (oncocytic) variants. The latter variants do not take up RAI.

Follicular carcinoma results from certain gene mutations or translocations. Aberrant DNA methylation, activation of the *ras* oncogene, and mutations of the *MEN1* gene can result in benign follicular adenomas. Loss of function of

PPAR or the *3P* tumor suppressor gene can lead to follicular carcinoma, and additional loss of the *p53* tumor suppressor gene can produce anaplastic carcinoma.

Follicular thyroid carcinoma and adenomas develop in patients with Cowden disease, a rare autosomal dominant familial syndrome caused by loss of a tumor suppressor gene; such patients tend to have macrocephaly, multiple hamartomas, early-onset breast cancer, intestinal polyps, facial papules, and other skin and mucosal lesions.

Medullary thyroid carcinoma represents about 3% of thyroid cancers. About one-third of cases are sporadic, one-third are familial, and one-third are associated with MEN type 2. Medullary thyroid carcinoma is often caused by an activating mutation of the *ret* oncogene on chromosome 10. Mutation analysis of the *ret* oncogene's exons 10, 11, 13, and 14 detects 95% of the mutations causing MEN 2A and 90% of the mutations causing familial medullary thyroid carcinoma. Patients with MEN 2B have activating mutations in exon 16 of the *ret* oncogene. These germline mutations can be detected by DNA analysis of peripheral WBCs. Therefore, discovery of a medullary thyroid carcinoma makes genetic analysis mandatory. If a gene defect is discovered, related family members must have genetic screening for that specific gene defect. When a family member with MEN 2A or familial medullary thyroid carcinoma does not have an identifiable *ret* oncogene mutation, gene carriers may still be identified using family linkage analysis. Even when no gene defect is detectable, family members should have regular thyroid surveillance. Somatic mutations of the *ret* oncogene can be identified in the tumors of 30% of patients with sporadic (nonfamilial) medullary thyroid carcinoma. (See Multiple Endocrine Neoplasia.)

Medullary thyroid carcinoma arises from parafollicular thyroid cells that can secrete calcitonin, prostaglandins, serotonin, ACTH, corticotropin-releasing hormone (CRH), and other peptides. These peptides can cause symptoms and can be used as tumor markers. Early local metastases are usually present, usually to adjacent muscle and trachea as well as to local and mediastinal lymph nodes. Eventually, late metastases may appear in the bones, lungs, adrenals, or liver. Medullary thyroid carcinoma does not concentrate iodine.

Anaplastic thyroid carcinoma represents about 2% of thyroid cancers. It usually presents in an older patient as a rapidly enlarging mass in a multinodular goiter. It is the most aggressive thyroid carcinoma and metastasizes early to surrounding nodes and distant sites. Local pressure symptoms include dysphagia or vocal cord paralysis. This tumor does not concentrate iodine.

Anaplastic thyroid carcinoma is caused by certain gene mutations, including inactivating mutations of the *p53* tumor suppressor gene, as described above for papillary and follicular thyroid carcinomas.

Other thyroid malignancies together represent about 3% of thyroid cancers. **Lymphoma** of the thyroid is more common in older women. Thyroid lymphomas are most commonly B cell lymphomas (50%) or mucosa-associated lymphoid tissue (MALT; 23%); other types include follicular, small lymphocytic, and Burkitt lymphoma and Hodgkin disease. Thyroidectomy is rarely required. **Other cancers** may sometimes metastasize to the thyroid, particularly bronchogenic, breast, and renal carcinomas and malignant melanoma.

Clinical Findings

Symptoms and Signs

Thyroid carcinoma usually presents as a palpable, firm, nontender nodule in the thyroid. Most thyroid carcinomas are asymptomatic, but large thyroid cancers can cause neck discomfort, dysphagia, or hoarseness (due to pressure on the recurrent laryngeal nerve). About 3% of thyroid malignancies present with a metastasis, usually to local lymph nodes but sometimes to distant sites such as bone or lung. Palpable lymph node involvement is present in 15% of adults and 60% of youths. Metastatic functioning differentiated thyroid carcinoma can sometimes secrete enough thyroid hormone to produce thyrotoxicosis. **Anaplastic thyroid carcinoma** is more apt to be advanced at the time of diagnosis, presenting with dysphagia, hoarseness, dyspnea, and metastases to the lungs. Occasionally, such carcinomas may be discovered while they are still relatively small and localized.

Medullary thyroid carcinoma frequently causes flushing and persistent diarrhea (30%), which may be the initial clinical feature. Patients with metastases often experience fatigue as well as other symptoms. Cushing syndrome develops in about 5% of patients from secretion of ACTH or CRH. Signs of pressure or invasion of surrounding tissues are present in anaplastic or large tumors; recurrent laryngeal nerve palsy can occur.

Lymphoma usually presents as a rapidly enlarging, painful mass arising out of a multinodular or diffuse goiter affected by autoimmune thyroiditis, with which it may be confused microscopically. About 20% of cases have concomitant hypothyroidism.

Laboratory Findings

(FNA biopsy is discussed above in the section on nodular thyroid.) Thyroid function tests are generally normal unless there is concomitant thyroiditis. Follicular carcinoma may secrete enough T_4 to suppress TSH and cause clinical hyperthyroidism.

Serum thyroglobulin is high in most metastatic papillary and follicular tumors, making this a useful marker for recurrent or metastatic disease. Caution must be exercised for the following reasons: (1) Circulating antithyroglobulin antibodies can cause erroneous thyroglobulin determinations. (2) Thyroglobulin levels may be misleadingly elevated in thyroiditis, which often coexists with carcinoma. (3) Certain thyroglobulin assays falsely report the continued presence of thyroglobulin after total thyroidectomy and tumor resection, causing undue concern about possible metastases. Therefore, unexpected thyroglobulin levels should prompt a repeat assay in another reference laboratory.

Serum calcitonin levels are usually elevated in medullary thyroid carcinoma, making this a marker for metastatic disease. However, serum calcitonin may be elevated in many other conditions, such as thyroiditis; pregnancy; azotemia; hypercalcemia; and other malignancies, including pheochromocytomas, carcinoid tumors, and carcinomas of the lung, pancreas, breast, and colon.

Serum calcitonin and carcinoembryonic antigen (CEA) determinations should be obtained before surgery for medullary carcinoma, then regularly in postoperative follow-up: every 4 months for 5 years, then every 6 months for life. Calcitonin levels remain elevated in patients with persistent tumor but also in some patients with apparent cure or indolent disease. Therefore, rising levels of calcitonin (or CEA) are the best indication for recurrence. Serum calcitonin levels > 250 pg/mL are also an indication for recurrent or metastatic medullary thyroid carcinoma. Serum CEA levels are usually elevated with medullary carcinoma, making this a useful second marker; however, it is not specific for this carcinoma.

Imaging

Ultrasound of the neck

Ultrasound of the neck should be performed routinely on all patients with thyroid cancer for the initial diagnosis and for follow-up. Ultrasound is useful in determining the size and location of the malignancy as well as the location of any neck metastases.

Radioactive iodine scanning

RAI (^{131}I or ^{123}I) thyroid and whole-body scanning is used after thyroidectomy for surveillance as described below, supplanting its previous use to determine whether a nodule was "cold" as a sign of malignancy.

CT scanning

CT scanning may demonstrate metastases and is particularly useful for localizing and monitoring lung metastases. However, CT scanning is less sensitive than ultrasound for detecting metastases within the neck. Iodinated contrast should never be given prior to RAI scanning or RAI therapy, since the large amounts of iodine in contrast media competitively inhibit the uptake of RAI by the thyroid, greatly reducing the effectiveness of subsequent RAI scanning and therapy. Medullary carcinoma in the thyroid, nodes, and liver may calcify, but lung metastases rarely do so.

MRI

MRI is particularly useful for imaging bone metastases.

PET scanning

PET scanning is particularly useful for detecting thyroid cancer metastases that do not have sufficient iodine uptake to be visible on RAI scans. Metastases are best detected using ^{18}FDG-PET whole-body scanning. The sensitivity of ^{18}FDG-PET scanning for differentiated thyroid cancer is enhanced if the patient is hypothyroid or receiving thyrotropin, which increases the metabolic activity of differentiated thyroid cancer. Disadvantages of PET scanning include its lack of specificity for thyroid cancer as well as its expense and lack of availability in many locations. ^{18}FDG-PET scanning has prognostic implications, since differentiated thyroid cancer metastases with low standard uptake value scores are associated with a better prognosis.

Differential Diagnosis

Neuroendocrine carcinomas may metastasize to the thyroid and be confused with medullary thyroid carcinoma.

False-positive ^{131}I scans are common with normal residual thyroid tissue and have been reported with Zenker diverticulum, struma ovarii, pleuropericardial cyst, gastric pull-up, and ^{131}I-contaminated bodily secretions. False-negative ^{131}I scans are common in early metastatic differentiated thyroid carcinoma but occur also in more advanced disease, including 14% of bone metastases.

Complications

The complications vary with the type of carcinoma. Differentiated thyroid carcinomas may have local or distant metastases. One-third of medullary carcinomas may secrete serotonin and prostaglandins, producing flushing and diarrhea, and may be complicated by the coexistence of pheochromocytomas or hyperparathyroidism. The risks of radical neck surgery include permanent hypoparathyroidism and vocal cord palsy due to recurrent laryngeal nerve damage; permanent hypothyroidism is expected after thyroidectomy and should always be treated adequately.

Treatment of Differentiated Thyroid Carcinoma

Surgical Treatment

Surgical removal is the treatment of choice for thyroid carcinomas. For differentiated papillary and follicular carcinoma, thyroidectomy with limited removal of cervical lymph nodes is adequate. The advantage of near-total thyroidectomy for differentiated thyroid carcinoma is that multicentric foci of carcinoma are more apt to be resected and there is then less normal thyroid tissue to compete with cancer for ^{131}I administered later for scans or treatment. Subtotal thyroidectomy is acceptable for adults under age 45 years who have a single small tumor (1 cm in diameter). Patients with bulky metastases in the neck region also benefit from surgery. Neck muscle resections are usually avoided for differentiated thyroid carcinoma. However, patients with the Hürthle cell variant of follicular carcinoma may benefit from a modified radical neck dissection. Metastases to the brain are best treated surgically, since treatment with radiation or RAI is ineffective. Levothyroxine is prescribed in doses of 0.05–0.1 mg/d immediately postoperatively (see Thyroxine Suppression and Chemotherapy, below). About 2–4 months after surgery, patients require reevaluation and often require therapy with ^{131}I (see below).

Highly skilled surgeons can perform near-total thyroidectomies with a less than 1% rate of serious complications (hypoparathyroidism or recurrent laryngeal nerve damage). Other series have reported up to an 11% incidence of permanent hypoparathyroidism after total thyroidectomy. The incidence of hypoparathyroidism may be reduced if accidentally resected parathyroids are immediately autotransplanted into the neck muscles.

Thyroidectomy requires at least an overnight hospital admission, since late bleeding, airway problems, and tetany can occur. Ambulatory thyroidectomy is potentially dangerous and should not be done.

Thyroxine Suppression and Chemotherapy

Patients who have had a thyroidectomy for differentiated thyroid cancer must take thyroxine replacement for life. Oral thyroxine should be given in doses that suppress serum TSH without causing clinical thyrotoxicosis. An ultrasensitive TSH assay should be used; serum TSH should be suppressed below 0.1 mU/L for patients with stage II disease and below 0.05 mU/L for patients with stage III–IV disease. (See Table 26–8.) Patients receiving thyroxine suppression therapy have been reported, as a group, to have slightly lower bone density than age-matched controls. However, for patients who are clinically euthyroid, thyroxine suppression therapy has a minimal effect upon bone and fracture risk. Nevertheless, patients receiving thyroxine suppression therapy are advised to have periodic bone densitometry.

Thyroid carcinomas are extraordinarily resistant to chemotherapy. Zoledronic acid, an intravenous bisphosphonate, has proven useful for osteolytic metastases from other solid tumors and has been used for patients with thyroid bone metastases, but its effectiveness is unknown.

Radioactive Iodine Therapy

Differentiated thyroid cancers variably retain the normal thyroid's ability to respond to TSH, secrete thyroglobulin, and concentrate iodine. Patients with stage II–IV cancer are usually treated with adjuvant ^{131}I therapy, when possible. The use of postoperative RAI therapy for patients with stage I differentiated thyroid cancer is controversial; there has been no demonstrable improvement in survival in this group of patients following RAI therapy. Most clinicians give RAI therapy to patients with stage I cancer only if the primary tumor was greater than 1–2 cm in diameter or of histologic higher risk.

About 2–4 months after thyroidectomy, patients follow a low iodine diet for at least 2 weeks before RAI therapy. **The low iodine diet** consists of avoiding the following: iodized table salt, sea salt, fish, shellfish, seaweed, commercial bread, dairy products, processed meats, canned or dried fruit, canned fruit juices, highly salted soups and snack foods, black tea, instant coffee, food coloring with Red Dye #3, egg yolks, multivitamins with iodine, or topical iodine. Patients must not be given intravenous radiologic contrast dyes containing iodine.

In order to stimulate radioiodine uptake by residual cancer tissue, patients are given recombinant human thyroid stimulating hormone (rhTSH, Thyrogen) as described below. Thyroxine withdrawal (2 weeks before ^{131}I therapy) is an alternative to Thyrogen, allowing the body's TSH levels to rise naturally and increasing the body's retention of administered ^{131}I. This technique avoids the high costs of Thyrogen. Also, whether Thyrogen-stimulated ^{131}I therapy is adequate to treat patients with stage III–IV cancer remains controversial. However, hypothyroidism is uncomfortable for most patients.

Just before ^{131}I therapy, serum is obtained for measurement of TSH (to make certain it is > 30 mcU/mL), thyroglobulin, and hCG (in all reproductive-age women). Pregnant women may not receive RAI therapy. Women are advised to avoid pregnancy for at least 4 months following ^{131}I therapy. Men have been found to have abnormal spermatozoa for up to 6 months following ^{131}I therapy and are advised to use contraceptive methods during that time.

^{131}I is administered orally. The dose of ^{131}I for thyroid "remnant ablation" in those with no nodal involvement is 30 mCi (1110 MBq). Higher doses (50–100 mCi) of ^{131}I may be given to patients with large primary tumors or tumors at the surgical margin. Patients with local lymph node involvement typically receive 100 mCi of ^{131}I; patients with more extensive neck node involvement or distant metastases receive ^{131}I at a dose of 125–200 mCi (4625–7400 MBq). A post-therapy whole-body scan, performed about 1 week after ^{131}I treatment, will often detect metastases that were not visible on pretreatment scans. Unfortunately, about 35% of patients with differentiated thyroid carcinoma have poor uptake of ^{131}I into metastases.

Patients who have been withdrawn from thyroid hormone may resume thyroxine at the full replacement dose 4 days following ^{131}I therapy. They may also cease their low iodine diet. To accelerate the return to euthyroidism, Cytomel may be added to thyroxine for 2 weeks at a dose of 25 mcg orally twice daily for 1 week, reduced to 12.5 mcg twice daily for the next week.

^{131}I therapy in doses over 100 mCi (3800 MBq) can cause gastritis, temporary oligospermia, sialadenitis, and xerostomia. RAI therapy can cause neurologic decompensation in patients with brain metastases; it is advisable to treat such patients with prednisone 30–40 mg orally daily for several days before and after ^{131}I therapy. Cumulative doses of ^{131}I over 500 mCi can cause infertility, pancytopenia (4%), and leukemia (0.3%). The kidneys excrete RAI. Patients receiving dialysis for kidney disease require a dosage reduction to only 20% of the usual dose of ^{131}I.

National Cancer Institute surveillance data for 30,278 patients with thyroid cancer has indicated that patients with differentiated thyroid cancer, treated with only surgery, had a 5% increased risk of developing a second non-thyroid malignancy (especially breast cancer). Patients with thyroid cancer who received ^{131}I therapy had a 20% increased risk of developing a second non-thyroid malignancy (especially leukemia and lymphoma). The greatest risk of second cancers appeared within 5 years of ^{131}I therapy and was most significant for younger patients.

Treatment of Other Thyroid Malignancies

Patients with anaplastic thyroid carcinoma are treated with local resection and radiation. Lovastatin, an HMG-CoA inhibitor, has been demonstrated to cause differentiation and apoptosis of anaplastic thyroid carcinoma cells in vitro; however, clinical studies have not been performed. Anaplastic thyroid carcinoma does not respond to ^{131}I therapy and is resistant to chemotherapy.

Patients with thyroid MALT lymphomas have a low risk of recurrence after simple thyroidectomy. Patients with other thyroid lymphomas are best treated with external radiation therapy; chemotherapy is added for extensive lymphoma. Patients with systemic lymphomas involving the thyroid are usually treated with chemotherapy.

Patients with a *ret* protooncogene mutation should have a prophylactic total thyroidectomy, ideally by age 6 years (MEN 2A) or at age 6 months (MEN 2B). Patients with medullary thyroid carcinoma are treated surgically; repeated neck dissections are often required over time. Medullary thyroid carcinomas do not respond to ^{131}I therapy and are generally resistant to chemotherapy.

External Radiation Therapy

External radiation may be delivered to bone metastases. Brain metastases do not usually respond to ^{131}I and are best resected or treated with gamma knife radiosurgery.

Surveillance

Patients with differentiated thyroid carcinoma must be observed long-term for recurrent or metastatic disease. Follow-up must include physical examinations and laboratory testing to ensure that patients remain clinically euthyroid with a suppressed TSH. To achieve suppression of serum TSH, the required dose of thyroxine may be such that serum FT_4 levels may be slightly elevated; in that case, measurement of serum T_3 or free T_3 (women who are pregnant or receiving oral estrogens) can be useful to ensure the patient is not frankly hyperthyroid.

Thyrotoxicosis can be caused by overreplacement with thyroxine or by the growth of functioning metastases.

Neck palpation has a sensitivity of only 16% for detecting cervical lymph node metastases. For surveillance, neck ultrasound and serum thyroglobulin determinations (baseline and rhTSH-stimulated) have largely repeated whole-body radioiodine scanning, which has a false-negative rate of about 80%. Follow-up intervals of 4–6 months are usually satisfactory.

Neck ultrasound

Neck ultrasound should be used in all patients with thyroid carcinoma to supplement neck palpation. It is prudent to perform a thyroid/neck ultrasound in all patients with thyroid cancer preoperatively, 3 months postoperatively, and regularly thereafter. Ultrasound is more sensitive for lymph node metastases than either CT or MRI scanning. Small inflammatory nodes may be detected postoperatively and do not necessarily indicate metastatic disease, but follow-up is necessary. Ultrasound-guided FNA biopsy should be performed on suspicious lesions.

Serum thyroglobulin (Tg)

Thyroglobulin is produced by normal thyroid tissue and by most differentiated thyroid carcinomas. It is only after a total or near-total thyroidectomy and ^{131}I remnant ablation that Tg becomes a useful tumor marker for patients with differentiated papillary or follicular thyroid cancer, particularly for patients who do not have serum anti-Tg antibodies. Anti-Tg antibodies mainly interfere with immunometric assays and interfere less with radioimmunoassays for Tg. Anti-Tg antibodies tend to persist but may become less evident several years after total thyroidectomy and during the last trimester of pregnancy.

Detectable levels of thyroglobulin are commonly encountered in patients who have had incomplete thyroidectomies and ^{131}I remnant ablations. Detectable thyroglobulin levels do not necessarily indicate the presence of residual or metastatic thyroid cancer. However, baseline or stimulated serum Tg levels 2 ng/mL indicate the need for a repeat neck ultrasound and further scanning with RAI or ^{18}FDG-PET. If serum Tg levels remain 2 ng/mL in the presence of normal scanning, it is prudent to repeat the serum Tg in a national reference laboratory. Rising serum levels of thyroglobulin are particularly worrisome.

In one series of patients with differentiated thyroid cancer following thyroidectomy, there was a 21% incidence of metastases in patients with serum Tg < 1 ng/mL (while receiving thyroxine for TSH suppression). Therefore, baseline serum Tg levels are inadequately sensitive and *stimulated* serum Tg measurements should be used and *always* with neck ultrasound. The usefulness of routinely doing a radioiodine scan (see below) in low-risk patients is controversial but continues to be done in many centers during stimulation following either rhTSH or thyroid hormone withdrawal, according to the protocols described below.

Radioactive iodine (RAI: ^{131}I or ^{123}I) whole-body scanning

Despite its limitations, RAI has traditionally been used to detect metastatic differentiated thyroid cancer and to determine whether the cancer is amenable to treatment with ^{131}I. RAI scanning is particularly useful for high-risk patients and those with persistent anti-thyroglobulin antibodies that make serum thyroglobulin determinations unreliable.

The ^{131}I isotope may be used in scanning doses of < 3 mCi (111 MBq) or given within 2 weeks of RAI treatment to avoid "stunning" metastases such that they take up less of the RAI therapy dose. The radioisotope ^{123}I may be used in scanning doses of 5 mCi (185 MBq), does not stun tumors, and allows single-photon emission computed tomography (SPECT) to better localize metastases. Initial RAI scanning is typically performed about 2–4 months following surgery for differentiated thyroid carcinoma. Whole-body scanning should be performed for at least 30 minutes for at least 140,000 counts and spot views of the neck should be obtained for at least 35,000 counts.

About 65% of metastases are detectable by RAI scanning, but only after optimal preparation: Patients should ideally have a total or near-total thyroidectomy, since any residual normal thyroid competes for RAI with metastases, which are less avid for iodine. To avoid nonradioactive iodine competitive inhibition of RAI uptake, intravenous iodinated contrast must be avoided for at least 2 months before scanning; patients must follow a low-iodine diet for at least 2 weeks before scanning and continue to limit iodine consumption until the scan is complete or until after ^{131}I therapy. In addition, patients must have high levels of TSH to stimulate metastases to take up more RAI, making them visible on scanning. This can be accomplished by administering synthetic rhTSH or by allowing the patient to become hypothyroid. The use of rhTSH has become more widespread for surveillance scanning and stimulated thyroglobulin determinations following thyroidectomy for differentiated thyroid carcinoma, due to its convenience for the patient. For stage I–II patients, it is reasonable to perform a rhTSH-stimulated scan and thyroglobulin level 2–3 months after the initial neck surgery; if the scan is negative and the serum thyroglobulin is < 2 ng/mL, the patient may be monitored with yearly neck ultrasound and serum thyroglobulin levels. For higher-risk patients, the rhTSH-stimulated thyroglobulin and RAI scan may be repeated about 1 year after surgery and then again if warranted.

Thyrotropin-stimulated serum Tg and radioiodine scanning

For surveillance, recombinant human thyrotropin-(Thyrogen; rhTSH) is given in order to increase the sensitivity of serum thyroglobulin and RAI scanning. The use of rhTSH is particularly suited to "low-risk" patients: those with a small papillary thyroid carcinoma who have had a total or near-total thyroidectomy and have no known local or distal metastases and a serum thyroglobulin < 1 mcg/L during thyroxine suppression of serum TSH. In about 21% of such low-risk patients, rhTSH stimulates serum thyroglobulin to above 2 mcg/L; such patients have a 23% risk of local neck metastases and a 13% risk of distant metastases. Stimulated radioiodine neck and whole-body scanning can detect only about half of these metastases because they are small or not avid for iodine.

Thyrotropin must be kept refrigerated and may be administered according to the following protocol: Thyroxine replacement is held for 2 days before rhTSH and for 3 days afterward. On Monday and Tuesday, thyrotropin 0.9 mg is administered intragluteally (not intravenously). On Wednesday, serum is drawn for TSH and thyroglobulin determinations. Immediately thereafter, RAI is administered in a scanning dose (see above). On Friday, serum is drawn for thyroglobulin and the whole-body scan is performed.

Side effects of thyrotropin injections include nausea (11%) and headache (7%). Hyperthyroidism can occur in patients with significant metastases or residual normal thyroid. Thyrotropin has caused neurologic deterioration in 7% of patients with central nervous system metastases.

The combination of thyrotropin-stimulated scanning and thyroglobulin levels detects a thyroid remnant or cancer with a sensitivity of 84%. However, the presence of anti-thyroglobulin antibodies renders the serum thyroglobulin determination uninterpretable. Thyrotropin stimulation does not prepare patients for ^{131}I treatment; they must be prepared for treatment by becoming hypothyroid as described below.

Thyroid withdrawal-stimulated serum Tg and radioiodine scanning

Recombinant human TSH (rhTSH, Thyrogen) has largely replaced thyroid withdrawal, as noted above. But thyroid hormone withdrawal is still used, allowing the patient to become hypothyroid; high levels of endogenous TSH stimulate the uptake of RAI and production of thyroglobulin by thyroid cancer or residual thyroid.

Serum thyroxine is held for 14 days. Prior to scanning, serum TSH is assayed to confirm that it is > 30 mcU/mL; serum hCG is assayed to screen for pregnancy; serum thyroglobulin titers are also determined. Following radioisotope scanning, or 4 days after ^{131}I therapy (see above), thyroxine therapy may be resumed at full replacement dose.

Patients with **differentiated thyroid carcinoma** have traditionally required at least two annual consecutively negative stimulated serum thyroglobulin determinations < 1 mcg/L and normal RAI scans (if done) and neck ultrasound before they are considered to be in remission. Patients with persistent RAI uptake restricted to the thyroid bed need not have repeated ^{131}I therapies if neck ultrasound appears benign and serum thyroglobulin is < 5 ng/mL. Further radioiodine or other scans may be required for patients with more aggressive papillary-follicular, follicular, or medullary thyroid carcinomas, prior metastases, rising serum thyroglobulin levels, or other evidence of metastases.

Patients often have a negative whole-body radioiodine scan but have serum thyroglobulin levels that are > 2 ng/mL. In such cases, another thyroglobulin assay should be sent to a different reference laboratory to confirm the accuracy of the thyroglobulin determination. Patients with serum Tg levels > 2 ng/mL require close continued monitoring. Those with progressively rising Tg levels are at high risk for occult thyroid cancer metastases. Other scanning methods may be used in an effort to detect such metastases.

Positron emission tomography scanning

PET whole-body scanning using ^{18}FDG-PET is a relatively sensitive method for detecting thyroid cancer metastases—particularly those that are not revealed on RAI scanning. PET scanning is particularly useful for detecting thyroid cancer metastases in patients with a detectable serum thyroglobulin (especially serum thyroglobulin levels > 10 ng/mL and rising) who have a normal whole-body RAI scan and an unrevealing neck ultrasound. PET scanning can be combined with a CT scan; the resultant PET/CT fusion scan is 60% sensitive for detecting metastases that are not visible by other methods. This scan is less sensitive for small brain metastases. ^{18}FDG-PET scanning detects the metabolic activity of tumor tissue; for differentiated thyroid carcinoma, this scan is more sensitive when the patient is pretreated with thyrotropin as described above. One problem with ^{18}FDG-PET scanning is its lack of specificity. For example, false-positives can occur with benign hepatic tumors, sarcoidosis, radiation therapy, suture granulomas, reactive lymph nodes, or inflammation at surgical sites that can persist for months. False-positive uptake can also occur in muscles and brown fat in the neck and shoulders, axillae, mediastinum, perinephric regions, intercostal paravertebral spaces, and paravertebral muscles. A fusion ^{18}FDG-PET/CT (noniodine contrast) scan improves specificity but cannot distinguish thyroid carcinoma from other unrelated malignancies that may be present concurrently. Smaller metastases are often present on PET scanning before becoming visible on CT or MRI scanning.

^{18}FDG-PET scanning is particularly sensitive for detecting medullary thyroid carcinoma metastases, and prescan thyrotropin does not improve the PET scan sensitivity for medullary thyroid carcinoma.

Other scanning

Thallium-201 (^{201}Tl) scans may be useful for detecting metastatic differentiated thyroid carcinoma when the ^{131}I scan is normal but serum thyroglobulin is elevated. MRI scanning is particularly useful for imaging metastases in the brain, mediastinum, or bones. CT scanning is useful for imaging and monitoring pulmonary metastases.

Staging & Prognosis

Staging and survival for **papillary thyroid cancer** is shown on Table 26–8. Papillary thyroid cancer carries a generally good prognosis, particularly for adults under age 45 years, despite the fact that about 15% of these patients are subsequently found to have metastases. The following characteristics imply a worse prognosis: older age, male sex, bone or brain metastases, large pulmonary metastases, and lack of ^{131}I uptake into metastases. Younger patients with pulmonary metastases tend to respond better to ^{131}I therapy than do older adults. Certain papillary histologic types are associated with a higher risk of recurrence: tall cell, columnar cell, and diffuse sclerosing types. Brain metastases are detected in 1%; they reduce median survival to 12 months, but the patient's prognosis is improved by surgical resection. Patients with a **follicular variant of papillary carcinoma** have a prognosis somewhere between that of papillary and follicular thyroid carcinoma.

Table 26–8. Pathologic tumor-node-metastasis (pTNM) staging and tumor-related approximate survival rates for adults with appropriately treated differentiated (papillary) thyroid carcinoma based upon patient age, primary tumor size and invasiveness (T), lymph node involvement (N), and distant metastases (M).[1]

Stage	**Description**	**Five-Year Survival**	**Ten-Year Survival**
1	Under 45: any T, any N, no M Over 45: T 1 cm,	99%	98%

	no N, no M		
2	Under 45: any T, any N, any M Over 45: T > 1 cm limited to thyroid, no N, no M	99%	90%
3	Over 45: T beyond thyroid capsule, no N, no M; or any T, regional N, no M	95%	75%
4	Over 45: any T, any N, any M	85%	65%

[1] Patients having a relatively worse prognosis include those with follicular thyroid carcinoma and those with familial differentiated thyroid carcinoma.

Patients with **follicular carcinoma** have a cancer mortality rate that is 3.4 times higher than patients with papillary carcinoma. The Hürthle cell variant of follicular carcinoma is even more aggressive. Patients with primary tumors over 1 cm in diameter who undergo limited thyroid surgery (subtotal thyroidectomy or lobectomy) have a 2.2-fold increased mortality over those having total or near-total thyroidectomies. Patients who have not received ^{131}I ablation have mortality rates that are increased twofold by 10 years and threefold by 25 years (over those who have received ablation). The risk of cancer recurrence is twofold higher in men than in women and 1.7-fold higher in multifocal than in unifocal tumors.

Medullary thyroid carcinoma is more aggressive than differentiated thyroid cancer but is typically fairly indolent. The overall 10-year survival rate is 90% when the tumor is confined to the thyroid, 70% for those with metastases to cervical lymph nodes, and 20% for those with distant metastases. Patients with sporadic disease usually have lymph node involvement noted at the time of diagnosis, whereas distal metastases may not be noted for years. For patients with medullary thyroid carcinoma who have metastases to lymph nodes, modified radical neck dissection is recommended. Familial cases or those associated with MEN 2A tend to be less aggressive; the 10-year survival rate is higher, in part due to earlier detection. Medullary thyroid carcinoma that is seen in MEN 2B is more aggressive, arises earlier in life, and carries a worse overall prognosis. Women with medullary thyroid carcinoma who are under age 40 years have a better prognosis. A better prognosis is also obtained in patients undergoing total thyroidectomy and neck dissection; radiation therapy reduces recurrence in patients with metastases to neck nodes. The mortality rate is increased 4.5-fold when primary or metastatic tumor tissue stains heavily for myelomonocytic antigen M-1. Conversely, tumors with heavy immunoperoxidase staining for calcitonin are associated with prolonged survival even in the presence of significant metastases.

Anaplastic thyroid carcinoma carries a 1-year survival rate of about 10% and a 5-year survival rate of about 5%. Patients with fully localized tumors on MRI have a better prognosis.

Localized lymphoma carries a 5-year survival of nearly 100%. Those with disease outside the thyroid have a 63% 5-year survival. However, the prognosis is better for those with the MALT type. Patients presenting with stridor, pain, laryngeal nerve palsy, or mediastinal extension tend to fare worse.

Iodine Deficiency Disorder & Endemic Goiter

Essentials of Diagnosis

- Common in regions of the world with low-iodine diets.
- High rate of congenital hypothyroidism and cretinism.
- Goiters may become multinodular and grow to great size.
- Most adults with endemic goiter are found to be euthyroid; however, some are hypothyroid or hyperthyroid.
- Impaired cognition and hearing may be subtle or severe in congenital hypothyroidism.

General Considerations

About 1 billion people are iodine deficient, having no access to iodized salt and living in areas with iodine-depleted soil. Severe iodine deficiency increases the risk of miscarriage and stillbirth. About 0.5% of live births in iodine-deficient areas have full-blown cretinism. Moderate iodine deficiency during gestation and infancy cause other manifestations of congenital hypothyroidism, such as deafness and short stature and permanently lowers a child's IQ by 10–15 points. Such children belong to the most isolated and impoverished families whose affected children serve to perpetuate the cycle of poverty in these areas.

Populations in areas of iodine deficiency have a high incidence of goiter. One such area is Pescopagano, Italy, where 60% of adults have goiters. Hyperthyroidism (present or past) occurred in 2.9%; hypothyroidism was overt in 0.2% and subclinical in 3.8%.

Although iodine deficiency is the most common cause of endemic goiter, certain foods (eg, sorghum, millet, maize, cassava), mineral deficiencies (selenium, iron), and water pollutants can themselves cause goiter or aggravate a goiter proclivity caused by iodine deficiency. In iodine-deficient patients, smoking can induce goiter growth. Pregnancy aggravates iodine deficiency and is associated with an increase in size of thyroid nodules and the emergence of new nodules. Some individuals are particularly susceptible to goiter owing to congenital partial defects in thyroid enzyme activity.

Clinical Findings

Symptoms and Signs

Endemic goiters may become multinodular and very large. Growth often occurs during pregnancy and may cause compressive symptoms.

Substernal goiters are usually asymptomatic but can cause tracheal compression, respiratory distress and failure, dysphagia, superior vena cava syndrome, gastrointestinal bleeding from esophageal varices, palsies of the phrenic or recurrent laryngeal nerves, or Horner syndrome. Cerebral ischemia and stroke can result from arterial compression or thyrocervical steal syndrome. Substernal goiters can rarely cause pleural or pericardial effusions. The incidence of significant malignancy is less than 1%.

Some patients with endemic goiter may become hypothyroid. Others may become thyrotoxic as the goiter grows and becomes more autonomous, especially if iodine is added to the diet.

Laboratory Findings

The serum T4 is usually normal. Serum TSH is generally normal. TSH falls in the presence of hyperthyroidism if a multinodular goiter has become autonomous in the presence of sufficient amounts of iodine for thyroid hormone synthesis. TSH rises with hypothyroidism. Thyroid RAI uptake is usually elevated, but it may be normal if iodine intake has improved. Serum levels of antithyroid antibodies are usually either undetectable or in low titers. Serum thyroglobulin is often elevated.

Differential Diagnosis

Endemic goiter must be distinguished from all other forms of nodular goiter that may coexist in an endemic region (see above).

Prevention

Iodine deficiency is prevented by adding iodine to commercial salt. In the United States, potassium iodide is used. Some tropical countries use potassium iodate, since it is more stable than potassium iodide in hot and humid climates. Iodized salt contains iodine at about 20 mg per kg salt. The minimum dietary requirement for iodine is about 50 mcg daily, with optimal iodine intake being 150–300 mcg daily. Iodine sufficiency is assessed by measurement of urinary iodide excretion, the target being more than 10 mcg/dL. Initiating iodine supplementation in an iodine-deficient area greatly reduces the emergence of new goiters but causes an increased frequency of hyperthyroidism during the first year.

Treatment

The addition of potassium iodide to table salt greatly reduces the prevalence of endemic goiter and cretinism but is less effective in shrinking established goiter. Concurrent deficiencies in both vitamin A and iodine increase the risk of endemic goiter and concurrent repletion of both iodide and vitamin A reduces goiter in endemic goiter regions.

Adults with large multinodular goiter may require thyroidectomy for cosmesis, compressive symptoms, or thyrotoxicosis. Following partial thyroidectomy in iodine-deficient geographic areas, there is a high goiter recurrence rate, so near-total thyroidectomy is preferred when surgery is indicated. Certain patients may be treated with ^{131}I for large compressive goiters.

Complications

Dietary iodine supplementation increases the risk of autoimmune thyroid dysfunction, which may cause hypothyroidism or hyperthyroidism. Excessive iodine supplementation increases the risk of goiter. Thyroxine suppression carries the risk of inducing hyperthyroidism, particularly in patients with autonomous multinodular goiters; therefore, thyroxine suppression should not be started in patients with a low TSH level. Rarely, Graves disease can develop 3–10 months after ^{131}I treatment in patients with large multinodular goiters.

Parathyroid & Related Disorders

Parathyroid hormone (PTH) increases osteoclastic activity in bone, increases the renal tubular reabsorption of calcium, and stimulates the synthesis of 1,25-dihydroxycholecalciferol by the kidney. Meanwhile, PTH inhibits the absorption of phosphate and bicarbonate by the renal tubule. All of these actions cause a net increase in serum calcium (see illustration).

Fig.

Main actions of PTH and 1,25-(OH)2D in the maintenance of calcium and phosphate homeostasis. (Modified and reproduced, with permission, from Chandrasoma P, Taylor CE: *Concise Pathology*, 2nd ed. Originally published by Appleton & Lange. Copyright © 1994 by The McGraw-Hill Companies, Inc.)

Hypoparathyroidism & Pseudohypoparathyroidism

Essentials of Diagnosis

- Tetany, carpopedal spasms, tingling of lips and hands, muscle and abdominal cramps, psychological changes.
- Positive Chvostek sign and Trousseau phenomenon.
- Serum calcium low; serum phosphate high; alkaline phosphatase normal; urine calcium excretion reduced.
- Low or low-normal serum PTH in presence of hypocalcemia.
- Serum magnesium may be low.

General Considerations

Acquired hypoparathyroidism is most commonly seen following thyroidectomy, when it is usually transient but may be permanent. It may also occur after multiple parathyroidectomies. Hypoparathyroidism may occur transiently after surgical removal of a parathyroid adenoma for primary hyperparathyroidism due to suppression of the remaining normal parathyroids and accelerated remineralization of the skeleton (hungry bone syndrome). Neck irradiation may rarely cause hypoparathyroidism.

Parathyroid deficiency may also be the result of damage from heavy metals such as copper (Wilson disease) or iron (hemochromatosis, transfusion hemosiderosis), granulomas, sporadic autoimmunity, Riedel thyroiditis, tumors, or infection.

Functional hypoparathyroidism may also occur as a result of magnesium deficiency (malabsorption, chronic alcoholism), which prevents the secretion of PTH. Correction of hypomagnesemia results in rapid disappearance of the condition.

PGA type I (PGA-1) is also known as autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy (APECED). PGA-1 presents in childhood with at least two of the following manifestations: candidiasis, hypoparathyroidism, or Addison disease. Cataracts, uveitis, alopecia, vitiligo, or autoimmune thyroid disease may also develop.

Fat malabsorption occurs in 20% of patients with PGA-1 and may present as weight loss, diarrhea, or malabsorption of vitamin D, a fat-soluble vitamin used to treat the hypoparathyroidism. The fat malabsorption may be due to a deficiency in the jejunal enteroendocrine cells that produce cholecystokinin, causing a reduction in bile acid secretion.

In **congenital hypoparathyroidism,** parathyroid cells have calcium-sensing receptors (CaSR) that sense the serum calcium concentration and suppress PTH secretion by way of G-protein-coupled mechanisms. Gain-of-function mutations (constitutive activation) of the *CaSR* gene suppress the parathyroid glands, resulting in hypocalcemia without elevations in serum PTH levels. Such mutations cause "autosomal dominant hypocalcemia with hypercalciuria" (ADHH) from deficient secretion of PTH. The prevalence of ADHH in the population is about 1 in 70,000, and it typically presents in infancy with hypocalcemic seizures.

Hypoparathyroidism, deafness, and renal dysplasia (HDR or Barakat) syndrome is an autosomal dominant condition caused by haploinsufficiency or mutations of the gene *GATA3*. The hypocalcemia is present from birth but may not be detected until the occurrence of mental retardation or hypocalcemic tetany. The mostly high-frequency deafness is present at birth. Various renal and vesicoureteral anomalies occur.

Hypoparathyroidism may also be seen in DiGeorge syndrome, along with congenital cardiac and facial anomalies; hypocalcemia usually presents with tetany in infancy, but some cases are not detected until adulthood.

Clinical Findings

Symptoms and Signs

Acute hypoparathyroidism causes tetany, with muscle cramps, irritability, carpopedal spasm, and convulsions; tingling of the circumoral area, hands, and feet is almost always present. Symptoms of the chronic disease are lethargy, personality changes, anxiety state, blurring of vision due to cataracts, parkinsonism, and mental retardation.

Chvostek sign (facial muscle contraction on tapping the facial nerve in front of the ear) is positive, and Trousseau phenomenon (carpal spasm after application of a sphygmomanometer cuff) is present (see illustration). Cataracts may occur; the nails may be thin and brittle; the skin is dry and scaly, at times with fungus infection (candidiasis), and there may be loss of hair (eyebrows); and deep tendon reflexes may be hyperactive. Papilledema and elevated cerebrospinal fluid pressure are occasionally seen. Teeth may be defective if the onset of the disease occurs in childhood.

Fig.

Position of fingers in carpal spasm due to hypocalcemic tetany. (Reproduced, with permission, from Ganong WF: *Review of Medical Physiology*, 16th ed. Originally published by Appleton & Lange. Copyright © 1993 by The McGraw-Hill Companies, Inc.)

Laboratory Findings

Serum calcium is low, serum phosphate high, urinary calcium low, and alkaline phosphatase normal. Serum calcium is largely bound to albumin. In hypoalbuminemia, the serum ionized calcium may be determined, but it has had surprisingly poor clinical utility. Alternatively, the serum calcium level can be corrected for serum albumin level as follows:

PTH levels are low. Serum magnesium should be determined since hypomagnesemia frequently accompanies hypocalcemia and may exacerbate symptoms and decrease parathyroid function.

Imaging

Radiographs or CT scans of the skull may show basal ganglia calcifications; the bones may be denser than normal (see CT scan). Cutaneous calcification may occur.

Fig.

Metastatic calcification of the globus pallidus and cerebellum. (Courtesy of C Grunfeld.)

Other Examinations

Slit-lamp examination may show early posterior lenticular cataract formation. The electrocardiogram (ECG) shows prolonged QT intervals and T wave abnormalities. Patients with chronic hypoparathyroidism tend to have increased bone mineral density, particularly in the lumbar spine.

Complications

Acute tetany with stridor, especially if associated with vocal cord palsy, may lead to respiratory obstruction requiring tracheostomy. The complications of chronic hypoparathyroidism largely depend on the duration of the disease. There may be associated autoimmunity causing sprue syndrome, pernicious anemia, or Addison disease. In long-standing cases, cataract formation and calcification of the basal ganglia are seen. Occasionally, parkinsonian symptoms or choreoathetosis develop. Ossification of the paravertebral ligaments may occur with nerve root compression; surgical decompression may be required. Seizures are common in untreated patients. Overtreatment with vitamin D and calcium may produce nephrocalcinosis and impairment of kidney function. Chronic hypocalcemia can cause heart failure.

Differential Diagnosis

Paresthesias, muscle cramps, or tetany due to respiratory alkalosis, in which the serum calcium is normal, can be confused with hypocalcemia. In fact, hyperventilation tends to accentuate hypocalcemic symptoms.

At times hypoparathyroidism is misdiagnosed as idiopathic epilepsy, choreoathetosis, or brain tumor (on the basis of brain calcifications, convulsions, choked disks) or, more rarely, as "asthma" (on the basis of stridor and dyspnea). In patients with hypoalbuminemia, serum levels of ionized calcium are normal.

Hypocalcemia may also be due to malabsorption of calcium, magnesium, or vitamin D; patients do not always have diarrhea. Hypocalcemia may also be caused by certain drugs: loop diuretics, plicamycin, phenytoin, alendronate, and foscarnet. In addition, hypocalcemia may be seen in cases of rapid intravascular volume expansion or due to chelation from transfusions of large volumes of citrated blood. It is also observed in patients with acute pancreatitis. Hypocalcemia may develop in some patients with certain osteoblastic metastatic carcinomas (especially breast, prostate) instead of the expected hypercalcemia. Hypocalcemia with hyperphosphatemia (simulating hypoparathyroidism) is seen in azotemia but may also be caused by large doses of intravenous, oral, or rectal phosphate preparations and by chemotherapy of responsive lymphomas or leukemias.

Hypocalcemia with hypercalciuria may be due to a familial syndrome involving a mutation in the calcium-sensing receptor; such patients have levels of serum PTH that are in the normal range, distinguishing it from hypoparathyroidism. It is transmitted as an autosomal dominant disorder. Such patients are hypercalciuric; treatment with calcium and vitamin D may cause nephrocalcinosis.

Congenital pseudohypoparathyroidism is a group of disorders characterized by resistance to PTH. There are several subtypes caused by different mutations involving the PTH receptor or its G protein or adenylyl cyclase. Renal tubular resistance to PTH causes hypercalciuria with resultant hypocalcemia. PTH levels are high and the PTH receptors in bone are typically not involved, such that bony changes of hyperparathyroidism may be evident. Various phenotypic abnormalities—classically, short stature, round face, obesity, short fourth metacarpals (see photograph), ectopic bone formation, and mental retardation—may be associated with congenital pseudohypoparathyroidism. Patients without hypocalcemia but sharing the phenotypic abnormalities are said to have "pseudopseudohypoparathyroidism."

Treatment

Emergency Treatment for Acute Attack (Hypoparathyroid Tetany)

This usually occurs after surgery and requires immediate treatment.

Airway

Be sure an adequate airway is present.

Intravenous calcium gluconate

Calcium gluconate, 10–20 mL of 10% solution intravenously, may be given *slowly* until tetany ceases. Ten to 50 mL of 10% calcium gluconate may be added to 1 L of 5% glucose in water or saline and administered by slow intravenous drip. The rate should be so adjusted so that the serum calcium is maintained between 8 mg/dL and 9 mg/dL.

Oral calcium

Calcium salts should be given orally as soon as possible to supply 1–2 g of calcium daily. Liquid calcium carbonate, 500 mg/5 mL, may be especially useful. The dosage is 1–3 g calcium daily. Calcium citrate contains 21% calcium, but a higher proportion is absorbed with less gastrointestinal intolerance.

Vitamin D preparations

(Table 26–9.) Therapy should be started as soon as oral calcium is begun. The active metabolite of vitamin D, 1,25-dihydroxycholecalciferol (calcitriol), has a very rapid onset of action and is not long-lasting if hypercalcemia occurs. It is of great use in the treatment of acute hypocalcemia. Therapy is commenced at a dosage of 0.25 mcg orally each morning with upward dosage titration to near normocalcemia. Ultimately, doses of 0.5–2 mcg/d are usually required.

Table 26–9. Vitamin D preparations used in the treatment of hypoparathyroidism.

	Available Preparations	**Daily Dose**	**Duration of Action**

Ergocalciferol ergosterol, (vitamin D2, Calciferol)	Capsules of 50,000 international units; 8000 international units/mL oral solution	2000–200,000 units	1–2 weeks
Cholecalciferol (vitamin D3)	Capsules of 50,000 international units not available commercially in United States; may be compounded	10,000–50,000 units	4–8 weeks
Calcitriol (Rocaltrol)	Capsules of 0.25 and 0.5 mcg; 1 mcg/mL oral solution; 1 mcg/mL for injection	0.25–4 mcg	$^{1}/_{2}$–2 weeks

Calcifediol (25-hydroxyvitamin D3), another option for treatment, has an intermediate onset and duration of action; the usual starting dose is 20 mcg/d orally.

Magnesium

If hypomagnesemia is present (chronic alcoholism, malnutrition, renal loss, drugs such as cisplatin, etc), it must be corrected to treat the resulting hypocalcemia. Acutely, magnesium sulfate is given intravenously, 1–2 g every 6 hours. Long-term magnesium replacement may be given as magnesium oxide tablets (600 mg), one or two per day, or as a combined magnesium and calcium preparation (CalMag, others).

Transplantation of cryopreserved parathyroid tissue removed during prior surgery

Transplantation restores normocalcemia in about 23% of cases.

Maintenance Treatment

The goal should be to maintain the serum calcium in a slightly low but asymptomatic range (8–8.6 mg/dL). This will minimize the hypercalciuria that would otherwise occur and provides a margin of safety against overdosage and hypercalcemia, which may produce permanent damage to kidney function. Calcium supplementation (1–2 g/d) is given, along with a vitamin D preparation.

Patients with chronic hypoparathyroidism must usually be treated with some type of vitamin D (Table 26–9). Vitamin D2 (ergocalciferol) is derived from plants and is commercially available. The usual dose ranges from 25,000 to 150,000 units/d. Vitamin D3 (cholecalciferol), the form of vitamin D that is naturally produced in unprotected human skin with UV sunlight exposure, is not generally commercially available in the United States in large doses but may be compounded. Vitamin D_3 is at least three times more bioavailable than vitamin D_2, so that appropriate dosing adjustments must be made when changing from one type of vitamin D to another. Both forms of vitamin D are slow-acting preparation, and if toxicity develops, hypercalcemia—treatable with hydration and prednisone—may persist for weeks after it is discontinued. Ergocalciferol and cholecalciferol usually produce a more stable serum calcium level than do the shorter-acting preparations.

PTH acts upon the kidney to increase tubular reabsorption of calcium. Therefore, patients with hypoparathyroidism are prone to hypercalciuria and calcium nephrolithiasis during treatment. Target serum calcium levels should be 8–8.6 mg/dL, keeping it mildly low to avoid hypercalciuria. It is prudent to monitor urine calcium with "spot" urine determinations and keep the level below 30 mg/dL if possible. Hypercalciuria may respond to oral hydrochlorothiazide, usually given with a potassium supplement.

Caution: Phenothiazine drugs should be administered with caution, since they may precipitate extrapyramidal symptoms in hypocalcemic patients. Furosemide should be avoided, since it may worsen hypocalcemia.

Prognosis

The outlook is good if the diagnosis is made promptly and treatment instituted. Any dental changes, cataracts, and brain calcifications are permanent. Periodic blood chemical evaluation is required, since changes in calcium levels may call for modification of the treatment schedule. Hypercalcemia that develops in patients with seemingly stable, treated hypoparathyroidism may be a presenting sign of Addison disease.

Shalitin S et al. Clinical heterogeneity of pseudohypoparathyroidism: from hyper- to hypocalcemia. Horm Res. 2008;70(3):137–44. [PMID: 18663313]

Shoback D. Clinical practice. Hypoparathyroidism. N Engl J Med. 2008 Jul;359(4):391–403. [PMID: 18650515]

Hyperparathyroidism

Essentials of Diagnosis

- Frequently detected incidentally by screening.
- Renal calculi, polyuria, hypertension, constipation, fatigue, mental changes.
- Bone pain; rarely, cystic lesions and pathologic fractures.
- Serum and urine calcium elevated; urine phosphate high with low to normal serum phosphate; alkaline phosphatase normal to elevated.
- Elevated PTH.

General Considerations

Primary hyperparathyroidism is characterized by chronic poorly regulated excessive secretion of PTH by one or more parathyroid glands that results in hypercalcemia. It is an increasingly recognized disorder, present in up to 0.1% of adult patients examined. It can be seen at any age but is more frequent in persons over the age of 50 years and is three times more common in women than in men.

The disease is caused by hypersecretion of PTH, usually by a single parathyroid adenoma (80%), and less commonly by hyperplasia by two or more parathyroid glands (20%), or carcinoma (1%). However, when hyperparathyroidism presents before age 30 years, there is a higher incidence of multiglandular disease (36%) and carcinoma (5%). The size of the parathyroid adenoma correlates with the serum PTH level.

Hyperparathyroidism is familial in about 10% of cases. Parathyroid hyperplasia may arise in MEN types 1, 2A, and 2B. In MEN 1, multiglandular hyperparathyroidism is usually the initial manifestation and ultimately occurs in 90% of affected individuals. Hyperparathyroidism in MEN 2A is less frequent that in MEN 1 and is usually milder. Familial hyperparathyroidism can also occur in the hyperparathyroidism-jaw tumor syndrome, a rare autosomal dominant familial condition in which parathyroid cystic adenomas or carcinomas are associated with ossifying fibromas of the mandible and maxilla as well as renal lesions (cysts, hamartomas, Wilms tumors). Affected individuals usually present with severe hypercalcemia as teenagers or young adults; the pathology is usually a single parathyroid adenoma. (See Table 26–16.)

Hyperparathyroidism results in the excessive excretion of calcium and phosphate by the kidneys. PTH stimulates renal tubular reabsorption of calcium; however, hyperparathyroidism causes hypercalcemia and an increase in calcium in the glomerular filtrate that overwhelms tubular reabsorption capacity, resulting in hypercalciuria. At least 5% of renal calculi are associated with this disease. Diffuse parenchymal calcification (nephrocalcinosis) is seen less commonly. Chronic bone resorption induced by excessive PTH in the circulation may produce diffuse demineralization, pathologic fractures, or cystic bone lesions throughout the skeleton ("osteitis fibrosa cystica") (see x-ray).

Fig.
Osteitis fibrosa cystica with resorption of the distal phalanges. (Courtesy of C Grunfeld.)

In chronic kidney disease, hyperphosphatemia and decreased renal production of 1,25-dihydroxycholecalciferol (1,25[OH]$_2$D$_3$) initially produce a decrease in ionized calcium. The parathyroid glands are stimulated (secondary hyperparathyroidism) and may enlarge, becoming autonomous (tertiary hyperparathyroidism). The bone disease seen in this setting is known as "renal osteodystrophy." Parathyroid hyperplasia in uremia can result in extremely high serum PTH levels that are associated with uremic vascular calcification. Hypercalcemia often occurs after kidney transplant.

Parathyroid carcinoma is a rare cause of hyperparathyroidism but is more common in patients with severe hypercalcemia (see x-ray). About 50% of parathyroid carcinomas are palpable.

management of osteitis fibrosa due to tertiary hyperparathyroidism. Mayo Clin Proc 1972:47:110.)

Clinical Findings

Symptoms and Signs

Hypercalcemia of hyperparathyroidism is typically discovered accidentally by routine chemistry panels. Many patients are asymptomatic or have mild symptoms that may be elicited only upon questioning. Parathyroid adenomas are usually so small and deeply located in the neck that they are almost never palpable; when a mass is palpated, it usually turns out to be an incidental thyroid nodule.

Symptomatic patients are said to have problems with "bones, stones, abdominal groans, psychic moans, with fatigue overtones." The manifestations are categorized as skeletal, urinary tract, and those associated with hypercalcemia.

Skeletal manifestations

Hyperparathyroidism causes a loss of cortical bone and a gain of trabecular bone. Significant bone demineralization is uncommon in mild hyperparathyroidism, but osteitis fibrosa cystica may present as pathologic fractures or as "brown tumors" or cysts of the jaw. More commonly, patients have bone pain and arthralgias.

Manifestations of hypercalcemia

Mild hypercalcemia may be asymptomatic. However, hypercalcemia has a variety of manifestations that become progressively worse with more severe hypercalcemia. Paresthesias, muscular weakness, and diminished deep tendon reflexes are examples of **neuromuscular manifestations. Central nervous system** manifestations include malaise, fatigue, intellectual weariness, depression, increased sleep requirement, progressing to cognitive impairment, disorientation, psychosis, or stupor. **Cardiovascular symptoms** that can indicate hypercalcemia are hypertension, prolonged P-R interval, shortened Q-T interval, sensitivity to arrhythmic effects of digitalis, bradyarrhythmias, heart block, asystole. **Renal** manifestations include polyuria and polydipsia, caused by hypercalcemia-induced nephrogenic diabetes insipidus. Calcium-containing kidney stones are reported in about 18% of those with newly discovered primary hyperparathyroidism. Nephrocalcinosis and kidney disease can occur. Gastrointestinal symptoms include anorexia, nausea, vomiting, abdominal pain, weight loss, constipation, and obstipation. Pancreatitis occurs in 3%. **Pruritus** may be present. **Calcium** may precipitate in the corneas ("band keratopathy"). Calcium may also precipitate in extravascular tissues as well as in small arteries, causing small vessel thrombosis and skin necrosis (calciphylaxis).

Hyperparathyroidism during pregnancy

About 67% of women with primary hyperparathyroidism during pregnancy experience complications such as nephrolithiasis, hyperemesis, pancreatitis, muscle weakness, cognitive changes, and hypercalcemic crisis. About 80% of fetuses experience complications of maternal hyperparathyroidism, including fetal demise, preterm delivery, low birth weight, postpartum neonatal tetany, and permanent hypoparathyroidism.

Laboratory Findings

The hallmark of primary hyperparathyroidism is the serum calcium > 10.5 mg/dL (Figure 26–1). In hyperproteinemic states, the total serum calcium may be elevated but the ionized fraction is normal, whereas in primary hyperparathyroidism, the ionized calcium is almost always over 5.4 mg/dL (1.4 mmol/L). In practice, serum ionized calcium determinations have not proved to be very helpful clinically. The serum phosphate is often low (< 2.5 mg/dL). The urine calcium excretion may be high or normal (averaging 250 mg/g creatinine) but it is usually low for the degree of hypercalcemia. There is an excessive loss of phosphate in the urine in the presence of hypophosphatemia (25% of cases). (In secondary hyperparathyroidism due to kidney disease, the serum phosphate is high.) The alkaline phosphatase is elevated only if bone disease is present. The plasma chloride and uric acid levels may be elevated. Vitamin D deficiency is common in patients with hyperparathyroidism, and it is prudent to screen for vitamin D deficiency with a serum 25-OH vitamin D determination. Low serum 25-OH vitamin D levels (< 20 mcg/L; < 50 nmol/L) can aggravate hyperparathyroidism and its bone manifestations; vitamin D replacement may be helpful in treating patients with hyperparathyroidism. (See below.)

Figure 26–1.

Parathyroid hormone and calcium nomogram. Relationship between serum intact parathyroid hormone (PTH) and serum calcium levels in patients with hypoparathyroidism, pseudohypoparathyroidism, nonparathyroid hypercalcemia, primary hyperparathyroidism (HPT), and secondary hyperparathyroidism. (Courtesy of GJ Strewler.)

Elevated serum levels of intact PTH (IRMA assay) confirm the diagnosis of hyperparathyroidism. Patients with apparent hyperparathyroidism should be screened for familial benign hypocalciuric hypercalcemia with a 24-hour urine for calcium and creatinine.

Patients should discontinue thiazide diuretics prior to this test. Calcium excretion of < 50 mg/24 hours (or < 5 mg/dL on a random urine) is not typical for primary hyperparathyroidism and indicates possible familial benign hypocalciuric hypercalcemia. (See below.)

Imaging

Preoperative sestamibi-iodine subtraction scanning and neck ultrasonography have been used to locate parathyroid adenomas in patients with hyperparathyroidism, in an effort to improve the outcome and limit the invasiveness of neck surgery. Parathyroid imaging is crucial for patients who have had prior neck surgery. However, the usefulness of preoperative parathyroid localizing imaging studies for first neck explorations remains controversial. Imaging is not useful for the diagnosis of hyperparathyroidism, which must be made by serum calcium and PTH determinations. Preoperative scanning does not improve the outcome of initial bilateral neck explorations performed by a surgeon with special expertise in parathyroid surgery. Therefore, preoperative imaging has been used mainly to improve the outcome for limited neck exploration, with only modest success. (See Surgical Parathyroidectomy, below.) Small benign thyroid nodules are discovered incidentally in nearly 50% of patients with hyperparathyroidism who have imaging with ultrasound or MRI.

CT and MRI scanning are not ordinarily required or useful for initial preoperative parathyroid localizing studies, since these scanning techniques are less sensitive for identifying tiny parathyroid adenomas. However, for repeat neck operations and when ectopic parathyroids are suspected, MRI is preferred since it offers better soft tissue contrast than CT scanning and is less adversely affected by postoperative changes in the neck. Three-dimensional technetium-99m sestamibi scanning can also help localize ectopic parathyroid glands.

Bone density measurements by dual energy x-ray absorptiometry (DXA) is helpful in determining the amount of bone loss in patients with hyperparathyroidism. Bone loss occurs mostly in long bones, and DXA should ideally include three areas: lumbar spine, hip, and distal radius.

Bone radiographs are usually normal and are not required to make the diagnosis of hyperparathyroidism. There may be demineralization, subperiosteal resorption of bone (especially in the radial aspects of the fingers) (see x-ray), or loss of the lamina dura of the teeth. There may be cysts throughout the skeleton, mottling of the skull ("salt-and-pepper appearance"), or pathologic fractures. Articular cartilage calcification (chondrocalcinosis) is sometimes found.

Fig.

A: Magnified x-ray of index finger on the fine-grain industrial film showing classic subperiosteal resorption in a patient with severe primary hyperparathyroidism. Note the left (radial) surface of the distal phalanx, where the cortex is almost completely resorbed, leaving only fine wisps of cortical bone. ***B:*** Skull x-ray from a patient with severe secondary hyperparathyroidism due to prolonged end-stage renal disease. Extensive areas of demineralization alternate with areas of increased bone density, resulting in an exaggerated picture of the "salt and pepper" skull x-ray, which used to be a classic finding in primary hyperparathyroidism. This is rarely seen now and cannot be visualized easily in x-ray reproductions. Although it is difficult to appreciate at this magnification, the dental lamina dura is absent—another classic x-ray finding in severe hyperparathyroidism. (Both films courtesy of H Genant.)

Patients with renal osteodystrophy may have ectopic calcifications around joints or in soft tissue. Such patients may exhibit radiographic changes of osteopenia, osteitis fibrosa, or osteosclerosis, alone or in combination.

Osteosclerosis of the vertebral bodies is known as "rugger jersey spine."

Complications

Pathologic long bone fractures are more common in patients with hyperparathyroidism than in the general population. Urinary tract infection due to stone and obstruction may lead to kidney disease and uremia. If the serum calcium level rises rapidly, clouding of sensorium, kidney disease, and rapid precipitation of calcium throughout the soft tissues may occur. Peptic ulcer and pancreatitis may be intractable before surgery. Insulinomas or gastrinomas may be associated, as well as pituitary tumors (MEN type 1). Pseudogout may complicate hyperparathyroidism both before and after surgical removal of tumors. Hypercalcemia during gestation produces neonatal hypocalcemia.

In tertiary hyperparathyroidism due to chronic kidney disease, high serum calcium and phosphate levels may cause disseminated calcification in the skin, soft tissues, and arteries (calciphylaxis); this can result in painful ischemic necrosis of skin and gangrene, cardiac arrhythmias, and respiratory failure. The actual serum levels of calcium and phosphate have not correlated well with calciphylaxis, but a calcium (mg/dL) x phosphate (mg/dL) product over 70 is usually present.

Differential Diagnosis

Artifact

A report of hypercalcemia may be due to laboratory error or excess tourniquet time and should always be repeated. Hypercalcemia may be due to high serum protein concentrations; in the presence of high or low serum albumin concentrations, a serum ionized calcium is more dependable than the total serum calcium concentration. Hypercalcemia may also be seen with dehydration; spurious elevations in serum calcium have been reported with severe hypertriglyceridemia, when the calcium assay uses spectophotometry.

Vitamin D Deficiency

Secondary hyperparathyroidism predictably develops in patients with a deficiency in vitamin D. Serum calcium levels are typically in the normal range, but may rise to become borderline elevated with time, due to parathyroid glandular hyperplasia. (See Osteomalacia section.)

Hypercalcemia of Malignancy

Many malignant tumors (breast, lung, pancreas, uterus, hypernephroma, paraganglioma, etc) can produce hypercalcemia. In some cases (breast carcinoma especially), bony metastases are present. In others, no metastases to bone can be demonstrated. Most of these tumors secrete PTH-related protein (PTHrP), which has tertiary structural homologies to PTH and causes bone resorption and hypercalcemia similar to those of PTH. The clinical features of the hypercalcemia of cancer can closely simulate hyperparathyroidism. Serum phosphate is often low, but the plasma level of PTH by IRMA is *low*. Serum PTHrP may be elevated.

Multiple myeloma is a common cause of hypercalcemia in the older population. Many other hematologic cancers, such as monocytic leukemia, T cell leukemia and lymphoma, and Burkitt lymphoma, have also been associated with hypercalcemia. Multiple myeloma causes kidney dysfunction; resultant increased levels of carboxyl terminal PTH may cause it to be confused with hyperparathyroidism if a carboxyl terminal PTH assay is used.

Sarcoidosis and Other Granulomatous Disorders

Macrophages and perhaps other cells present in granulomatous tissue have the ability to synthesize $1{,}25(OH)_2D3$. Hypercalcemia has been reported in patients with sarcoidosis, tuberculosis, berylliosis, histoplasmosis, coccidioidomycosis, leprosy, and even foreign-body granuloma. Increased intestinal calcium absorption and hypercalciuria are more common than hypercalcemia. Serum levels of $1{,}25(OH)_2D_3$ are elevated.

Calcium or Vitamin D Ingestion

Ingestion of large amounts of calcium or vitamin D can cause hypercalcemia, especially in patients who concurrently take thiazide diuretics, which reduce urinary calcium loss. Hypercalcemia is reversible following withdrawal of calcium and vitamin D supplements. If hypercalcemia persists, the possibility of associated hyperparathyroidism should be strongly considered.

In vitamin D intoxication, patients may be taking large amounts of vitamin D for unclear reasons, so a thorough review of all medications is important. Hypercalcemia may persist for several weeks. Serum levels of 25-hydroxycholecalciferol (25[OH]D_3) are helpful to confirm the diagnosis. A brief course of corticosteroid therapy may be necessary if hypercalcemia is severe.

Familial Benign Hypocalciuric Hypercalcemia

Familial benign hypocalciuric hypercalcemia can be easily mistaken for mild hyperparathyroidism. It is a common autosomal dominant inherited disorder (prevalence: 1 in 16,000) caused by a loss-of-function mutation in the gene encoding the CaSR. CaSRs are found on the surface of the parathyroid glands and allow the parathyroid glands to vary PTH secretion according to serum calcium levels. Reduced function of the CaSR causes the parathyroid glands to falsely "sense" hypocalcemia and inappropriately release slightly excessive amounts of PTH. At the same time, the renal tubule CaSRs are also affected, causing hypocalciuria. Familial benign hypocalciuric hypercalcemia is characterized by hypercalcemia, hypocalciuria (usually < 50 mg/24 h), variable hypermagnesemia, and normal or minimally elevated levels of PTH. These patients do not normalize their hypercalcemia after subtotal parathyroid removal and should not be subjected to surgery. The condition has an excellent prognosis and is easily diagnosed with a family history and urinary calcium clearance determination.

Adrenal Insufficiency

Hypercalcemia is common in untreated Addison disease. This is partly due to disinhibition of calcium uptake by the renal tubule and gut. Additionally, Addison disease can cause dehydration and hyperproteinemia, resulting in higher levels of nonionized calcium.

Hyperthyroidism

Increased bone turnover is a feature of thyrotoxicosis. Mild hypercalcemia may also be present.

Other Causes

Other causes of hypercalcemia are shown in Table 21–8. Modest hypercalcemia is also occasionally seen in patients taking thiazide diuretics or lithium; such patients may have an inappropriately nonsuppressed PTH level with hypercalcemia. Prolonged immobilization at bed rest may also cause hypercalcemia, especially in adolescents and patients with extensive Paget disease of bone. Hypercalcemia is noted in up to one-third of acutely ill patients being treated in intensive care units, particularly patients with acute renal injury. Serum PTH levels are usually slightly elevated, consistent with mild hyperparathyroidism. Bisphosphonates can increase serum calcium in 20% and serum PTH becomes high in 10%, mimicking hyperparathyroidism.

Treatment

Surgical Parathyroidectomy

Parathyroidectomy is recommended for patients with symptomatic hyperparathyroidism, kidney stones, bone disease, and pregnancy.

Some patients with seemingly asymptomatic hyperparathyroidism may be surgical candidates for other reasons such as (1) serum calcium 1 mg/dL above the upper limit of normal with urine calcium excretion > 50 mg/24 h (off thiazide diuretics), (2) urine calcium excretion over 400 mg/24 h, (3) cortical bone density (wrist, hip) 2 SD below normal, (4) relative youth (under age 50–60 years), (5) difficulty ensuring medical follow-up, or (6) pregnancy. During pregnancy, parathyroidectomy is performed in the second trimester.

Patients who undergo surgery for "asymptomatic" hyperparathyroidism have been reported to have modest benefits in social and emotional function, with improvements in anxiety and phobias being reported in comparison to similar patients who are monitored without surgery.

Preoperative parathyroid imaging has been used in an attempt to allow unilateral minimally invasive neck surgery. The usefulness of preoperative parathyroid imaging was evaluated in a series of 350 patients with sporadic primary hyperparathyroidism. A single gland was predicted by sestamibi in 83%, by ultrasound in 85%, and by concordance of both in 59% of patients. Unilateral neck exploration, directed by these studies, resulted in success rate of only 73%, 77%, and 82%, respectively, despite the intraoperative quick PTH assay predicting success. Even in patients with concordant sestamibi and ultrasound scans, and an intraoperative PTH drop of > 50%, at least one additional abnormal parathyroid gland is left behind in the contralateral neck in 15% of patients.

Bilateral neck exploration is usually advisable for all patients without preoperative localization studies for the following: (1) patients with a family history of hyperparathyroidism, (2) patients with a personal or family history of MEN, and (3) patients wanting an optimal chance of success with a single surgery. Patients undergoing unilateral neck exploration can have the incision widened for bilateral neck exploration if two abnormal glands are found or if the serum quick PTH falls by < 50%. Parathyroid glands are not uncommonly supernumerary (five or more) or ectopic (eg, intrathyroidal, carotid sheath, mediastinum).

Parathyroid hyperplasia is commonly seen with uremic calciphylaxis. When surgery is performed, a subtotal parathyroidectomy is optimally treated surgically; three and one-half glands are usually removed, and a metal clip is left to mark the location of residual parathyroid tissue.

Parathyroid carcinoma can cause severe hypercalcemia associated with very high serum levels of PTH. Preoperative localizing studies usually detect a large invasive tumor. Therapy consists of en bloc resection of the tumor and the ipsilateral thyroid lobe. Metastases to local and to distant sites occur in about 50% of patients. Reoperation for neck recurrence is usually necessary. Adjuvant treatment includes radiation therapy. Intravenous bisphosphonate (zoledronic acid) and calcimimetic agents (NPS R-568) are used for treatment of hypercalcemia.

Complications: Serum PTH levels fall below normal in 70% of patients within hours after successful surgery, commonly causing hypocalcemic paresthesias or even tetany. Hypocalcemia tends to occur the evening after surgery or on the next day. Therefore, frequent postoperative monitoring of serum ionized calcium (or serum calcium plus albumin) is advisable beginning the evening after surgery. Once hypercalcemia has resolved, liquid or chewable calcium carbonate is given orally to reduce the likelihood of hypocalcemia. Symptomatic hypocalcemia is treated with larger doses of calcium; calcitriol (0.25–1 mcg daily orally) may be added, with the dosage depending on symptom severity. Magnesium salts are sometimes required postoperatively, since adequate magnesium is required for functional recovery of the remaining suppressed parathyroid glands.

In about 12% of patients having successful parathyroid surgery, PTH levels rise above normal (while serum calcium is normal or low) by 1 week postoperatively. This secondary hyperparathyroidism is probably due to "hungry bones" and is treated with calcium and vitamin D preparations. Such therapy is usually needed only for 3–6 months but is required long-term by some patients.

Hyperthyroidism commonly occurs immediately following parathyroid surgery. It is caused by release of stored thyroid hormone during surgical manipulation of the thyroid. Short-term treatment with propranolol may be required for several days.

Medical Measures

Fluids

Hypercalcemia is treated with a large fluid intake unless contraindicated. Severe hypercalcemia requires hospitalization and intensive hydration with intravenous saline. (See Chapter 21: Fluid & Electrolyte Disorders.)

Bisphophonates

Intravenous bisphosphonates are potent inhibitors of bone resorption and can temporarily treat the hypercalcemia of hyperparathyroidism, malignancy, or immobilization. They may relieve bone pain as with patients with metastatic breast or prostate cancer. Pamidronate in doses of 30–90 mg (in 0.9% saline) is administered intravenously over 2–4 hours. Zoledronic acid 2–4 mg is administered intravenously over 15 to 20 minutes; it is quite effective but also very expensive. These drugs cause a gradual decline in serum calcium over several days that may last for weeks to months. Such intravenous bisphosphonates are used generally for patients with severe hyperparathyroidism in preparation for surgery. Oral bisphosphonates, such as alendronate, are not effective for treating the hypercalcemia or hypercalciuria of hyperparathyroidism. However, oral alendronate has been shown to improve bone mineral density in the lumbar spine and hip (not distal radius) and may be used for asymptomatic patients with hyperparathyroidism who have a low bone mineral density.

Cinacalcet

Cinacalcet hydrochloride is a calcimimetic agent that binds to sites of the parathyroid glands' extracellular CaSRs to increase their affinity for extracellular calcium, thereby decreasing PTH secretion. Cinacalcet may be administered orally in doses of 30–250 mg daily. Patients with primary hyperparathyroidism have also been treated successfully with cinacalcet in oral doses of 30–50 mg twice daily, with 73% of patients achieving normocalcemia. Administering cinacalcet for secondary parathyroidism of kidney disease causes a drop of serum PTH levels to < 250 pg/mL in 41% of patients receiving dialysis. Cinacalcet is given to patients with severe hypercalcemia due to parathyroid carcinoma at initial doses of 30 mg orally twice daily and increased progressively to 60 mg twice daily, then 90 mg twice daily to a maximum of 90 mg every 6–8 hours. Cinacalcet is usually well tolerated but may cause nausea and vomiting, which are usually transient. It is very expensive.

Vitamin D and vitamin D analogs

Primary hyperparathyroidism

For patients with vitamin D deficiency, careful vitamin D replacement may be beneficial to patients with hyperparathyroidism. Aggravation of hypercalcemia does not ordinarily occur. Serum PTH levels may fall with vitamin D replacement in doses of 800–2000 units daily. Occasionally, larger doses are required to achieve normal 25-OH vitamin D levels.

Secondary and tertiary hyperparathyroidism associated with kidney disease

Calcitriol, given orally or intravenously after dialysis, suppresses parathyroid hyperplasia of kidney disease. Certain vitamin D analogs suppress PTH secretion but cause less hypercalcemia than calcitriol. *Doxercalciferol* (Hectorol) is administered three times weekly orally with hemodialysis to patients with azotemic secondary hyperparathyroidism in the following doses according to serum immunoradiometric PTH (iPTH) levels: give 10 mcg three times weekly for iPTH > 400 pg/mL and increase the dose by 2.5 mcg every 8 weeks if iPTH remains > 300 pg/mL, to a maximum dose of 20 mcg three times weekly. If iPTH drops to < 100 pg/mL, doxercalciferol is held for 1 week and the dose is reduced by at least 2.5 mcg. *Paricalcitol* (Zemplar) is administered intravenously during dialysis three times weekly in starting doses of 0.04–0.1 mcg/kg body weight; the dosage is increased for iPTH levels > 300 pg/mL to a maximum dose of 0.24 mcg/kg three times weekly;

paricalcitol is held if iPTH levels drop to < 100 pg/mL.

Other measures

Patients with mild, asymptomatic hyperparathyroidism may be monitored closely medically. Such patients are advised to keep active, avoid immobilization, and drink adequate fluids. They need to avoid thiazide diuretics, large doses of vitamins A, and calcium-containing antacids or supplements. Serum calcium and albumin are checked about twice yearly, kidney function and urine calcium once yearly, and three-site bone density (distal radius, hip, and spine) every 2 years.

Estrogen replacement, given to postmenopausal women, reduces hypercalcemia slightly. Similarly, raloxifene also reduces the hypercalcemia of hyperparathyroidism, reducing serum calcium levels an average of 0.4 mg/dL. Propranolol may be useful for preventing the adverse cardiac effects of hypercalcemia.

Renal osteodystrophy is caused by secondary or tertiary hyperparathyroidism during kidney disease. It can be prevented or delayed by reducing hyperphosphatemia with phosphate binding medication and dietary phosphate restriction.

Monitoring Patients with Asymptomatic Primary Hyperparathyroidism

Patients with mild asymptomatic hyperparathyroidism may not need therapy. However, they should be monitored closely for the development of symptoms of hypercalcemia and worsening hypercalcemia. Patients should be evaluated every 6 months with determination of blood pressure and serum calcium. Rising serum calcium should prompt further evaluation and determination of PTH levels. Serum creatinine should be measured yearly. A bone density should ideally be determined every 1 to 2 years at 3 points: wrist, hip, and vertebrae.

Prognosis

Completely asymptomatic patients with mild hypercalcemia may be observed and treated medically without compromising survival. There can be unexplained exacerbations and partial remissions. Surgical removal of sporadic parathyroid adenomas generally results in a permanent cure. Patients with MEN 1 undergoing subtotal parathyroidectomy may experience long remissions, but hyperparathyroidism usually recurs.

Spontaneous cure due to necrosis of the tumor has been reported but is exceedingly rare. The bones, in spite of severe cyst formation, deformity, and fracture, will heal if a parathyroid tumor is successfully removed. The presence of pancreatitis increases the mortality rate. Acute pancreatitis usually resolves with correction of hypercalcemia, whereas subacute or chronic pancreatitis tends to persist. Significant renal damage may progress even after removal of an adenoma. Parathyroid carcinoma tends to invade local structures and may sometimes metastasize; repeat surgical resections and radiation therapy can prolong life. Aggressive surgical and medical management of parathyroid carcinoma can result in an 85% 5-year survival rate and a 57% 10-year survival rate.

Vanderwalde LH et al. Effect of bone mineral density and parathyroidectomy on fracture risk in primary hyperparathyroidism. World J Surg. 2009 Mar;33(3):406–11. [PMID: 18763015]

Metabolic Bone Disease: Introduction

The term "metabolic bone disease" denotes those conditions producing diffusely decreased bone density and diminished bone strength. It is categorized by histologic appearance: osteoporosis (bone matrix and mineral both decreased) and osteomalacia (bone matrix intact, mineral decreased). Osteoporosis and osteomalacia often coexist in the same patient.

Osteoporosis

Essentials of Diagnosis

- Asymptomatic to severe backache from vertebral fractures.
- Spontaneous fractures often discovered incidentally on radiography; loss of height.
- Serum PTH, calcium, phosphorus, and alkaline phosphatase usually normal.
- Serum 25-hydroxyvitamin D levels often low as a comorbid condition.
- Demineralization, especially of spine, hip, pelvis, and wrist.

General Considerations

Osteoporosis is estimated to cause 1.5 million fractures annually in the United States—mainly of the spine and hip. The morbidity and indirect mortality rates are very high. Since the usual form of the disease is clinically evident in middle life and beyond and since women are more frequently affected than men, it is often referred to as "postmenopausal" osteoporosis. It is characterized by a decrease in the amount of bone present to a level below which it is capable of maintaining the structural integrity of the skeleton. The rate of bone formation is often normal, whereas the rate of bone resorption is increased.

Osteoporosis can be caused by a variety of factors. The long-term use of a selective serotonin reuptake inhibitor (SSRI) has been associated with reduced hip density, increased falls, and increased fracture risk, particularly in the elderly. Rosiglitazone appears to decrease bone mineral density in men with type 2 diabetes mellitus. The causes of osteoporosis are listed in Table 26–10.

Table 26–10. Causes of osteoporosis.[1]

Hormone deficiency	**Genetic disorders**
Estrogen (women)	Aromatase deficiency
Androgen (men)	Type I collagen mutations
Hormone excess	Osteogenesis imperfecta
Cushing syndrome or corticosteroid administration	Idiopathic juvenile and adult osteoporosis
Thyrotoxicosis	Ehlers–Danlos syndrome
Hyperparathyroidism	Marfan syndrome

Immobilization and microgravity	Homocystinuria
Tobacco	**Miscellaneous**
Alcoholism	Celiac disease
Malignancy, especially multiple myeloma	Anorexia nervosa
Medications	Protein-calorie malnutrition
Excessive vitamin D intake	Vitamin C deficiency
Excessive vitamin A intake	Hyponatremia (chronic)
Heparin therapy	Copper deficiency
Selective serotonin reuptake inhibitors	Liver disease
Rosiglitazone	Rheumatoid arthritis
	Uncontrolled diabetes mellitus
	Systemic mastocytosis

[1] See Table 26–11 for causes of osteomalacia.

Osteoporosis is caused by a reduction and disarray of bone's microarchitectural organic collagenous matrix, which normally accounts for about 40% of bone mass and provides bone's tensile strength. Inorganic calcium and phosphate compounds, largely calcium hydroxyapetite, mineralize the available collagenous bone matrix and normally provide about 60% of bone mass and most of bone's compressive strength.

Osteogenesis imperfecta is caused by a major mutation in the gene encoding for type I collagen, the major collagen constituent of bone. This causes severe osteoporosis; spontaneous fractures occur in utero or during childhood. Blue sclerae may be present. Certain polymorphisms in the genes encoding type I collagen are common, particularly in whites, resulting in collagen disarray and predisposing to hypogonadal (eg, menopausal) or idiopathic osteoporosis.

Clinical Findings

Symptoms and Signs

Osteoporosis is usually asymptomatic until fractures occur. It may present as backache of varying degrees of severity or as a spontaneous fracture or collapse of a vertebra. Loss of height is common. Once osteoporosis is identified, a carefully directed history and physical examination must be performed to determine its cause (Table 26–10).

Laboratory Findings

Serum calcium, phosphate, and PTH are normal. The alkaline phosphatase is usually normal but may be slightly elevated, especially following a fracture. Vitamin D deficiency is very common and serum determination of 25-hydroxyvitamin D should be obtained for every individual with low bone density. Serum 25-hydroxyvitamin D levels below 20 ng/mL are considered frank vitamin D deficiency. Lesser degrees of vitamin D deficiency (serum 25-hydroxyvitamin D levels between 20 ng/mL and 30 ng/mL) may also increase the risk for hip fracture. (See Osteomalacia, below.) Testing for thyrotoxicosis and hypogonadism may be required. Celiac disease may be screened for with serum immunoglobulin A (IgA) endomysial antibody and tissue transglutaminase antibody determinations.

Bone Densitometry

DXA is used to determine the bone density of the lumbar spine and hip. Bone densitometry should be performed on all patients who are at risk for osteoporosis or osteomalacia or have pathologic fractures or radiographic evidence of diminished bone density. This test delivers negligible radiation, and the measurements are quite accurate. However, bone densitometry cannot distinguish osteoporosis from osteomalacia; in fact, both are often present. Also, the bone mineral density does not directly measure bone quality and is only fairly successful at predicting fractures. Vertebral bone mineral density may be misleadingly high in compressed vertebrae and in patients with extensive arthritis. DXA also overestimates the bone mineral density of taller persons and underestimates the bone mineral density of smaller persons. Quantitative CT delivers more radiation but is more accurate in the latter situations.

See Related Guideline from *CURRENT Practice Guidelines in Primary Care 2009*

Bone mineral density in typically expressed in gm/cm^2, for which there are different normal ranges for each bone and for each type of DXA-measuring machine. The "T score" is a simplified way of reporting bone density in which the patient's bone mineral density is compared to the young normal mean and expressed as a standard deviation score. The World Health Organization has established criteria for defining osteoporosis in postmenopausal white women, based on T score:

> T score –1.0: Normal.
> T score –1.0 to –2.5: Osteopenia ("low bone density").
> T score < –2.5: Osteoporosis.
> T score < –2.5 with a fracture: Severe osteoporosis.

This classification is somewhat arbitrary and there really is no bone mineral density fracture threshold; instead, the fracture risk increases about twofold for each standard deviation drop in bone mineral density. In fact, most women with fragility fractures have bone densities above –2.5. Surveillance DXA bone densitometry is recommended for postmenoapausal women with a frequency according to their T scores: obtain DXA every 5 years for T scores –1.0 to –1.5, every 3–5 years for scores –1.5 to –2.0, and every 1–2 years for scores under –2.0.

The "Z score" is used to express bone density in premenopausal women, younger men, and children. The Z score is a statistical term that is used for expressing an individual's bone density as standard deviation from age-matched, race-matched, and sex-matched means.

Differential Diagnosis

Osteoporosis has many causes (see Table 26–10). Additionally, osteopenia and fractures can be caused by osteomalacia (see below) and bone marrow neoplasia such as myeloma or metastatic bone disease. These conditions coexist in many patients.

Treatment

Specific Measures

Several treatment options are available, so a regimen is tailored to each patient. Generally, treatment is indicated for all women with osteoporosis (T scores below –2.5) and for all patients who have had fragility fractures. Prophylactic treatment should also be considered for patients with advanced osteopenia (T scores between –2.0 and –2.5).

See Related Guideline from *CURRENT Practice Guidelines in Primary Care 2009*

Vitamin D and calcium

Osteoporosis and osteomalacia often coexist (see Osteomalacia section). Sun exposure and vitamin D supplementation are useful in preventing and treating osteomalacia. Vitamin D supplementation reduces the incidence of vertebral fractures by 37% and may slightly reduce the incidence of nonvertebral fractures. Oral vitamin D is given in doses of 800-2000 international units daily. Higher doses of vitamin D may be required during winter months and for patients having prolonged hospitalization or nursing home care, for patients with serum levels of 25-hydroxyvitamin D below 20 ng/mL, and those with intestinal malabsorption.

Calcium supplementation has not reduced the fracture risk in otherwise healthy postmenopausal women. Therefore, calcium supplementation is indicated principally for those with diets low in calcium. More important is the assurance of adequate vitamin D through sun exposure or oral vitamin D supplementation, and calcium supplementation should include vitamin D. Calcium supplementation may be given as calcium citrate (0.4–0.7 g elemental calcium per day) or calcium carbonate (1–1.5 g elemental calcium per day).

Bisphosphonates

Bisphosphonates work similarly, inhibiting osteoclast-induced bone resorption. They increase bone density significantly and reduce the incidence of both vertebral and nonvertebral fractures. Bisphosphonates have also been effective in preventing corticosteroid-induced osteoporosis. To ensure intestinal absorption, oral bisphosphonates must be taken in the morning with at least 8 oz of plain water at least 40 minutes before consumption of anything else. The patient must remain upright after taking bisphosphonates to reduce the risk of esophagitis. These medications are excreted in the urine. However, no dosage adjustments are required for patients with creatinine clearances above 35 mL/min. There has been little experience giving bisphosphonates to patients with severe kidney disease; if given, the dose would need to be greatly reduced and serum phosphate levels monitored.

Bisphosphonates may be given orally once monthly or weekly; which is more convenient than daily therapy and equally effective. Available oral preparations include **alendronate,** 70 mg orally once weekly (tablet or solution), and **risedronate,** 35 mg orally once weekly. Both these medications reduce the risk of both vertebral and nonvertebral fractures. Studies sponsored by the manufacturer of alendronate found that alendronate was significantly more potent than risedronate and equally well tolerated. Another bisphosphonate, **ibandronate sodium**, is taken once monthly in a dose of 150 mg orally. Once-monthly ibandronate is convenient and reduces the risk of vertebral fractures but not nonvertebral fractures; its effectiveness has not been directly compared with other bisphosphonates. Oral bisphosphonates can cause esophagitis, especially in patients with hiatal hernia and gastroesophageal reflux.

For patients who cannot tolerate oral bisphosphonates or for whom oral bisphosphonates are contraindicated, intravenous bisphosphonates are available. **Zoledronic acid** is a third-generation bisphosphonate and a potent osteoclast inhibitor. It can be given every 12 months in doses of 2–4 mg intravenously over 15–30 minutes. **Pamidronate** is an older parenteral bisphosphonate that can be given in doses of 30–60 mg by slow intravenous infusion in normal saline solution every 3–6 months. Transient postinfusion fever occurs fairly commonly (26%).

Both oral and parenteral bisphosphonates can cause bone, joint, or muscle pains as well as fatigue, particularly after the first dose. The onset of pain may occur from 1 day to 1 year after therapy is initiated, with a mean of 14 days. The pain can be transient, lasting several days and usually resolving spontaneously but typically recurring with subsequent doses. When the bisphosphonate is discontinued, most patients experience gradual relief of pain. Some patients taking alendronate or risedronate for osteoporosis have experienced bone osteonecrosis: painful, necrotic, nonhealing lesions of the jaw, particularly after tooth extraction. The incidence of osteonecrosis is very low. In a prospective 3-year trial of 7714 women who received intravenous zoledronic acid 5 mg/y or placebo, there were no cases of osteonecrosis. For such patients with painful exposed bone, treatment is 90% effective (without resolution of the exposed bone) using antibiotics along with 0.12% chlorohexidine antiseptic mouth wash. Patients receiving bisphosphonates must receive regular dental care and try to avoid dental extraction. Osteonecrosis of the jaw has also been reported in patients receiving intravenous zoledronic acid and pamidronate for treatment of hypercalcemia and bone metastases, for which the drugs had been administered more frequently than for osteoporosis. Another adverse effect reported with bisphosphonates is ocular inflammation, manifested by blurred vision, eye pain, uveitis, conjunctivitis, and scleritis, which remits after discontinuation of the drug. Other side effects can include nausea, anemia, dyspnea, and leg edema. In patients taking bisphosphonates, hypercalcemia is seen in 20% and serum PTH levels increase above normal in 10%, mimicking primary hyperparathyroidism.

The half-life of alendronate in bone is 10 years. Therefore, patients with mild osteoporosis may discontinue bisphosphonates after a 5-year course of therapy. Bone density falls in 18% of patients during their first year of treatment with bisphosphonates, but 80% of such patients have gain in bone density with continued bisphosphonate treatment.

Sex hormones

Hypogonadal women who take estrogen replacement therapy (ERT) have a lower risk of developing osteoporosis. Postmenopausal estrogen replacement is valuable as an osteoporosis prevention measure and this should be one factor in the complex decision about whether to take ERT. Low doses of estrogen appear to be adequate to prevent postmenopausal osteoporosis (see Estrogen Replacement Therapy). Once osteoporosis has developed, estrogen replacement is not an effective treatment. Although ERT does increase bone mineral density in postmenopausal women with osteoporosis, it has not been demonstrated to significantly reduce fracture rates. Men with hypogonadism may be treated with testosterone (see Male Hypogonadism).

Selective estrogen receptor modulators

Raloxifene, 60 mg/d orally, can be used by postmenopausal women in place of estrogen for prevention of osteoporosis. Bone density increases about 1% over 2 years in postmenopausal women versus 2% increases with estrogen replacement. It reduces the risk of vertebral fractures by about 40% but does not appear to reduce the risk of nonvertebral fractures. Raloxifene produces a reduction in LDL cholesterol but not the rise in high-density lipoprotein (HDL) cholesterol seen with estrogen. It has no direct effect on coronary plaque. Unlike estrogen, raloxifene does not reduce hot flushes; in fact, it often intensifies them. It does not relieve vaginal dryness. Unlike estrogen, raloxifene does not cause endometrial hyperplasia, uterine bleeding, or cancer, nor does it cause breast soreness. The risk of breast cancer is reduced 76% in women taking raloxifene for 3 years. Since it is a potential teratogen, it is relatively contraindicated in women capable of pregnancy.

Raloxifene increases the risk for thromboembolism and should not be used by women with such a history. Leg cramps can also occur.

Teriparatide

Teriparatide (Forteo, Parathar) is an analog of PTH. Teriparatide stimulates the production of new collagenous bone matrix that must be mineralized. Patients receiving teriparatide must have sufficient intake of vitamin D and calcium. When administered to patients with osteoporosis in doses of 20 mcg/d subcutaneously for 2 years, teriparatide dramatically improves bone density in most bones except the distal radius. The recommended dose should not be exceeded, since teriparatide has caused osteosarcoma in rats when administered in very high doses. Patients with Paget disease of bone or patients with open epiphyses or hypercalcemia should not use the drug. Patients with a past history of osteosarcoma or chondrosarcoma should not use this medication. Side effects may include dizziness and leg cramps. Teriparatide is approved only for a 2-year course of treatment.

Precautions: Hypercalcemia may develop in patients who are taking teriparatide if they also take corticosteroids and thiazide diuretics along with oral calcium supplementation.

Following a course of teriparatide, a course of bisphosphonates should be considered in order to retain the improved bone density.

Calcitonin

A nasal spray of calcitonin-salmon (Miacalcin) is available that contains 2200 units/mL in 2-mL metered-dose bottles. The usual dose is one puff (0.09 mL, 200 international units) once daily, alternating nostrils. Nasal administration causes significantly less nausea and flushing than the parenteral route. However, nasal symptoms such as rhinitis and epistaxis occur commonly; other less common adverse reactions include flu-like symptoms, allergy, arthralgias, back pain, and headache. Five years of therapy increases bone 2–3% and reduces the number of new vertebral fractures. Both nasal and parenteral calcitonin have analgesic effects on bone pain; reduction of pain may be noted within 2–4 weeks after commencing therapy. Calcitonin reduces the incidence of vertebral fractures, but its effect upon nonvertebral fractures has not been established.

Denosumab

Denosumab is a promising treatment for osteoporosis that is in clinical trials. It is a monoclonal antibody that inhibits osteoclast activation by binding to the osteoclasts' receptor activator of nuclear factor-kappa B ligand (RANKL). Denosumab is effective at doses of 60 mg subcutaneously every 6 months. It has been relatively well tolerated, with an 8% incidence of flu-like symptoms.

General Measures

For prevention and treatment of osteoporosis, the diet should be adequate in protein, total calories, calcium, and vitamin D. Pharmacologic corticosteroid doses should be reduced or discontinued if possible. Thiazides may be useful if hypercalciuria is present. High-impact physical activity (eg, jogging) significantly increases bone density in men and women. Stair-climbing increases bone density in women. Patients who cannot exercise vigorously should be encouraged to engage in other exercise regularly, thereby increasing strength and reducing the risk of falling. Weight training is helpful to increase muscle strength as well as bone density. Measures should be taken to avoid falls at home (eg, adequate lighting, handrails on stairs, handholds in bathrooms). Patients who have weakness or balance problems must use a cane or a walker; rolling walkers should have a brake mechanism. Balance exercises can reduce the risk of falls. Patients should be kept active; bedridden patients should be given active or passive exercises. The spine may be adequately supported (though braces or corsets are usually not well tolerated), but rigid or excessive immobilization must be avoided. Alcohol and smoking should be avoided.

See Related Guideline from *CURRENT Practice Guidelines in Primary Care 2009*

Prognosis

Bone mineral density densitometries can detect whether progressive osteopenia or frank osteoporosis is developing. Hypogonadal women, especially those not receiving HRT, must ensure sufficient intake of vitamin D to prevent osteomalacia. Bisphosphonates and raloxifene can reverse progressive osteopenia and osteoporosis and decrease fracture risk.

Hypogonadal men are also at risk for developing osteoporosis. Testosterone administration can prevent osteoporosis. Men with prostate cancer may not receive testosterone replacement and should be monitored with bone densitometries. Bisphosphonate therapy can reverse progressive osteopenia and osteoporosis in men.

Osteomalacia

Essentials of Diagnosis

- Painful proximal muscle weakness (especially pelvic girdle); bone pain and tenderness.

- Decreased bone density from defective mineralization.
- Laboratory abnormalities may include increases in alkaline phosphatase, decreased 25-hydroxyvitamin D, or hypocalcemia, hypocalciuria, hypophosphatemia, secondary hyperparathyroidism.
- Classic radiologic features may be present.

General Considerations

Defective mineralization of the growing skeleton in childhood causes permanent bone deformities (rickets). Defective skeletal mineralization in adults is known as osteomalacia.

It is caused by any condition that results in inadequate calcium or phosphate mineralization of bone osteoid.

Etiology

(See Table 26–11.)

Table 26–11. Causes of osteomalacia.[1]
Vitamin disorders
Decreased availability of vitamin D
Insufficient sunlight exposure
Nutritional deficiency of vitamin D

Malabsorption; aging, excess wheat bran, bariatric surgery, pancreatic enzyme deficiency
Nephrotic syndrome
Vitamin D–dependent rickets type I
Liver disease
Chronic kidney disease
Kidney transplantation
Phenytoin, carbamazepine, or barbiturate therapy
Dietary calcium deficiency
Phosphate deficiency
Decreased intestinal absorption
Nutritional deficiency of phosphorus
Malabsorption
Phosphate-binding antacid therapy
Increased renal loss
X-linked hypophosphatemic rickets
Tumoral hypophosphatemic osteomalacia
Association with other disorders, including paraproteinemias, glycogen storage diseases, neurofibromatosis, Wilson disease, Fanconi syndrome, renal tubular acidosis, and alcoholism
Disorders of bone matrix
Hypophosphatasia

Fibrogenesis imperfecta
Axial osteomalacia
Inhibitors of mineralization
Aluminum
Bisphosphonates

Modified, with permission, from Fitzgerald PA: *Handbook of Clinical Endocrinology*, 2nd ed. McGraw-Hill, 1992.

[1] See Table 26–10 for causes of osteoporosis.

Vitamin D Deficiency and Resistance

Vitamin D deficiency decreases the intestinal absorption of calcium and is the most common cause of osteomalacia. Significant vitamin D deficiency (serum 25[OH]D < 50 nmol/L or < 20 ng/mL) was found in 24.3% of postmenopausal women from 25 countries in the MORE study. The incidence varied: < 1% in Southeast Asia, 29% in the United States, and 36% in Italy. Severe vitamin D deficiency (serum 25[OH]D < 25 nmol/L or < 10 ng/mL) was found in 4% of these women; 3.5% in the United States and 12.5% in Italy. Vitamin D deficiency is particularly common in the institutionalized elderly, with the incidence exceeding 60% in some groups not receiving vitamin D supplementation. Deficiency of vitamin D may arise from insufficient sun exposure, malnutrition, or malabsorption (due to pancreatic insufficiency, cholestatic liver disease, sprue, inflammatory bowel disease, jejunoileal bypass, Billroth type II gastrectomy, etc). Cholestyramine binds bile acids necessary for vitamin D absorption. Patients with severe nephrotic syndrome lose large amounts of vitamin D-binding protein in the urine, and osteomalacia may also develop.

Anticonvulsants (eg, phenytoin, carbamazepine, valproate, phenobarbital) inhibit the hepatic production of 25(OH)D and sometimes cause osteomalacia. Phenytoin can also directly inhibit bone mineralization. Serum levels of 1,25(OH)$_2$D are usually normal.

Vitamin D–dependent rickets type I is caused by a rare autosomal recessive disorder with a defect in the renal enzyme 1- -hydroxylase leading to defective synthesis of 1,25(OH)$_2$D. It presents in childhood with rickets and alopecia; osteomalacia develops in adults with this condition unless treated with oral calcitriol in doses of 0.5–1 mcg daily.

Vitamin D–dependent rickets type II (better known as hereditary 1,25[OH]$_2$D-resistant rickets) is caused by a genetic defect in the 1,25(OH)$_2$D receptor. Patients have hypocalcemia with childhood rickets and adult osteomalacia. Alopecia is common. These patients respond variably to oral calcitriol in very large doses (2–6 mcg daily).

Deficient Calcium Intake

Rickets and osteomalacia continue to be common problems in many tropical countries despite adequate exposure to sunlight. A nutritional deficiency of calcium can occur in any severely malnourished patient. Some degree of calcium deficiency is common in the elderly, since intestinal calcium absorption declines with age. Ingestion of excessive wheat bran also causes calcium malabsorption.

Phosphate Deficiency

Phosphatonin is a circulating peptide that inhibits sodium-dependent phosphate transport in the renal tubule; high levels of this peptide cause excessive phosphaturia, resulting in hypophosphatemia. X-linked hypophosphatemic rickets is associated with high levels of phosphatonin, probably caused by familial or sporadic mutations in PHEX endopeptidase, which fails to cleave phosphatonin.

Oncogenic osteomalacia is caused by excessive production of phosphatonin by a wide variety of soft tissue tumors (87% benign). Such tumors may be hard to find. OctreoScan has been reported to detect many of these small tumors. The condition is characterized by hypophosphatemia, excessive phosphaturia, reduced or normal serum 1,25$(OH)_2D$ concentrations, and osteomalacia. Excessive renal phosphate losses are also seen in proximal renal tubular acidosis and Fanconi syndrome. Some cases of hyperphosphaturia are idiopathic.

Other causes of hypophosphatemic osteomalacia include poor nutrition, alcoholism, or chelation of phosphate in the gut by aluminum hydroxide antacids, calcium acetate (Phos-Lo), or sevelamer hydrochloride (Renagel).

Aluminum Toxicity

Bone mineralization is inhibited by aluminum. Osteomalacia may occur in patients receiving long-term renal hemodialysis with tap water dialysate or from aluminum-containing antacids used to reduce phosphate levels. Osteomalacia may develop in patients being maintained on long-term total parenteral nutrition if the casein hydrolysate used for amino acids contains high levels of aluminum.

Hypophosphatasia

Hypophosphatasia , a deficiency of bone alkaline phosphatase effect, is a rare genetic cause of osteomalacia that is commonly misdiagnosed as osteoporosis. The incidence in the United States is about 1 in 100,000 live births; about 1 in 300 adults is a carrier. Many different mutations in the gene (designated *ALPL*) encoding bone alkaline phosphatase have been described, and transmission can be either autosomal recessive or autosomal dominant. The phenotypic presentation of hypophosphatasia is extremely variable. At its worst extreme, it can present as a stillborn without dentition or calcified bones. At its mildest, hypophosphatasia can present in middle age with premature loss of teeth, foot pain (due to metatarsal stress fractures), thigh pain (due to femoral pseudofractures), or arthritis (due to chondrocalcinosis). Serum alkaline phosphatase (collected in a non-EDTA tube) is low for age in patients with hypophosphatasia. To confirm the diagnosis, a 24-hour urine should be assayed for phosphoethanolamine, a substrate for tissue-nonspecific alkaline phosphatase, whose excretion is always elevated in patients with hypophosphatasia. Prenatal genetic testing, by way of chorionic villus biopsy, is available for the infantile form of hypophosphatasia. There is no proven therapy for hypophosphatasia, except for supportive care. Teriparatide, a useful therapy for osteoporosis, has been administered to some patients with hypophosphatasia, but its long-term efficacy is unknown.

Fibrogenesis Imperfecta Ossium

This rare condition sporadically affects middle-aged patients, who present with progressive bone pain and pathologic fractures. Bones have a dense "fishnet" appearance on radiographs. Serum alkaline phosphatase levels are elevated. Some patients have a monoclonal gammopathy, indicating a possible plasma cell dyscrasia causing an impairment in osteoblast function and collagen disarray. Remission has been reported after repeated courses of melphalan, corticosteroids, and vitamin D analog over 3 years.

Clinical Findings

The clinical manifestations of defective bone mineralization depend on the age at onset and the severity. In adults, osteomalacia is typically asymptomatic at first. Eventually, bone pain occurs, along with muscle weakness due to calcium deficiency. Pathologic fractures may occur with little or no trauma. Vitamin D deficiency has also been associated with a possible increased risk of multiple sclerosis, rheumatoid arthritis, and diabetes mellitus (types 1 and 2).

Diagnostic Tests

Serum is obtained for calcium, albumin, phosphate, alkaline phosphatase, PTH, and 25[OH]D_3 determinations. Bone densitometry helps document the degree of osteopenia. Radiographs may show diagnostic features (see x-ray).

Fig.

A: X-rays of the radius and ulna of a patient with severe osteomalacia, showing healing of a pseudofracture *(arrows)* during 7 months of treatment with ergocalciferol. ***B:*** X-ray of the pelvis, showing pseudofractures (Looser's zones, or Milkman's fractures) in a woman with severe osteomalacia. (Courtesy of G Gordan.)

In one series of biopsy-proved osteomalacia, alkaline phosphatase was elevated in 94% of patients; the calcium or phosphorus was low in 47% of patients; 25(OH)D3 was low in 29% of patients; pseudofractures were seen in 18% of patients; and urinary calcium was low in 18% of patients. $1,25(OH)_2D_3$ may be low even when $25(OH)D_2$ levels are normal.

Differential Diagnosis

Osteomalacia is often seen together with osteoporosis, and its presence can be inferred by finding low serum levels of 25(OH) vitamin D, low serum calcium, or low serum phosphate. A high serum alkaline phosphatase may be present in severe osteomalacia but not osteoporosis.

The relative contribution of the two entities to diminished bone density may not be apparent until treatment, since a dramatic rise in bone density is often seen with therapy for osteomalacia. Phosphate deficiency must be distinguished from hypophosphatemia seen in hyperparathyroidism.

Bone densitometry by DXA may give a misleadingly low reading for patients who are unusually slender with small bones. It must also be remembered that bone density only approximates bone tensile strength.

Prevention & Treatment

To obtain adequate sunshine vitamin D, the face, arms, hands, or back must have sun exposure without sunscreen for 15 minutes at least twice weekly. The main natural food source of vitamin D is fish, particularly, salmon, mackerel, cod liver oil, and sardines or tuna canned in oil. Most commercial cow's milk is fortified with vitamin D at about 400 international units per quart; however, skim milk and other dairy products contain much less vitamin D. Vitamin supplements containing vitamin D are widely available, but contain plant-derived vitamin D2, which has less biologic availability than once believed. In sunlight-deprived individuals (eg, veiled women, confined patients, or residents of higher latitudes during winter), the recommended daily allowance should be 1000 international units daily. In such individuals, vitamin D supplements should be given prophylactically. Patients receiving long-term phenytoin therapy may be treated prophylactically with vitamin D, 50,000 international units orally every 2–4 weeks.

Frank vitamin D deficiency is treated with ergocalciferol (D_2), 50,000 international units orally once or twice weekly for 6–12 months, followed by 1000–2000 international units daily. Some patients require long-term supplementation with ergocalciferol of up to 50,000 international units weekly. In patients with intestinal malabsorption, oral doses of 25,000–100,000 international units of vitamin D_2 daily may be required. Some patients with steatorrhea respond better to oral $25(OH)D_3$ (calcifediol), 50–100 mcg/d.

Beyond increasing the intestinal absorption of calcium, vitamin D supplementation may have additional effects. Vitamin D supplementation has been associated with improved muscle strength and a reduced fall risk, factors that reduce the risk of bone fracture.

The addition of calcium supplements to vitamin D is probably not necessary for the prevention of osteomalacia in the majority of otherwise well-nourished patients. However, patients with malabsorption or poor nutrition should receive calcium supplementation. Recommended doses of calcium are as follows: calcium citrate (eg, Citracal), 0.4–0.6 g elemental calcium per day, or calcium carbonate (eg, OsCal, Tums), 1–1.5 g elemental calcium per day. Calcium supplements are best administered with meals.

In hypophosphatemic osteomalacia, nutritional deficiencies are corrected, aluminum-containing antacids are discontinued, and patients with renal tubular acidosis are given bicarbonate therapy. In patients with sporadic adult-onset hypophosphatemia, hyperphosphaturia, and low serum 1,25$(OH)_2D$ levels, a search is conducted for occult tumors that may be resected; whole-body MRI scanning may be required.

For those with X-linked or idiopathic hypophosphatemia and hyperphosphaturia, oral phosphate supplements must be given long-term; calcitriol, 0.25–0.5 mcg/d, is given also to improve the impaired calcium absorption caused by the oral phosphate. Human recombinant growth hormone reduces phosphaturia and may be added to the above regimen.

Paget Disease of Bone (Osteitis Deformans)

Essentials of Diagnosis

- Often asymptomatic.
- Bone pain may be the first symptom.
- Kyphosis, bowed tibias, large head, deafness, and frequent fractures.
- Serum calcium and phosphate normal; alkaline phosphatase elevated; urinary hydroxyproline elevated.
- Dense, expanded bones on radiographs.

General Considerations

Paget disease of bone is a common condition manifested by one or more bony lesions having high bone turnover and disorganized osteoid formation. Involved bones become vascular, weak, and deformed. Paget disease is most common in the United Kingdom but is also common in other areas of the world, particularly in those with British ancestry. It is uncommon in Africa, Asia, and

Scandinavia. Paget disease is present in 1–2% of the population of the United States and affects men more commonly than women. It is usually diagnosed in patients over age 40 years and its prevalence doubles with each decade thereafter, reaching an incidence of about 10% after age 80. It is usually discovered incidentally during radiology imaging or because of incidentally discovered elevations in serum alkaline phosphatase. The cause of Paget disease is unknown. However, there is often a genetic component since about 15% of affected patients have a first-degree relative with the disease. Similar familial disorders occur at an earlier age and their genetics has been established (see Differential Diagnosis).

Clinical Findings

Symptoms and Signs

Paget disease is often mild and asymptomatic. Only 27% of affected individuals are symptomatic at the time of diagnosis. It can involve just one bone (monostotic) or multiple bones (polyostotic), particularly the skull, femur, tibia, pelvis, and humerus. The affected bones are typically involved right away and the disease tends not to involve additional bones during its course. Pain is the usual first symptom. It may occur in the involved bone or in an adjacent joint, which can be involved with degenerative arthritis. The bones can become soft, leading to bowed tibias, kyphosis, and frequent "chalkstick" fractures with slight trauma. If the skull is involved, the patient may report headaches and an increased hat size. Deafness may occur. Increased vascularity over the involved bones causes increased warmth and can cause vascular "steal" syndromes (see Complications).

Laboratory Findings

Serum alkaline phosphatase is usually markedly elevated. However, some patients with limited monostotic involvement may have serum alkaline phosphatase levels within the normal range. A serum bone-specific alkaline phosphatase determination can be useful for patients with a normal serum total alkaline phosphatase level and to distinguish the source of an elevated serum alkaline phosphatase as being from bone (rather than liver). Other markers of bone turnover may be elevated. Serum C-telopeptide (CTx) is usually high. Urinary hydroxyproline is also elevated in active disease. Serum calcium may be elevated, particularly if the patient is at bed rest. A serum 25-OH vitamin D determination should be obtained to screen for vitamin D deficiency, which can also present with an increased alkaline phosphatase and bone pain. Also, any vitamin D deficiency should be corrected before prescribing a bisphosphonate.

Imaging

On radiographs, the initial lesions are typically osteolytic, with focal radiolucencies ("osteoporosis circumscripta") in the skull or advancing flame-shaped lytic lesions in long bones (see x-ray). Bone lesions may subsequently become sclerotic and have a mixed lytic and sclerotic appearance. The affected bones eventually become thickened and deformed. Technetium pyrophosphate bone scans are helpful in delineating activity of bone lesions even before any radiologic changes are apparent (see CT scan).

Fig.

X-rays of the right femur in a patient with juvenile Paget disease before *(left)* and after *(right)* 10 months of treatment with calcitonin. Note the advancing V-shaped resorption front *(arrow)*. A striking improvement in the appearance of diseased bone is seen after treatment. Differential Diagnosis

Certain rare familial osteoclastic bone disorders share phenotypic homologies with Paget disease of bone. Familial expansile osteolysis, familial early-onset Paget disease, and familial skeletal hyperphosphatasia are autosomal dominant disorders caused by different tandem duplications of the gene encoding RANK, resulting in its constitutive activation. Juvenile Paget disease is an autosomal recessive disorder caused by an inactivating mutation in the gene encoding osteoprotegerin. The syndrome of Paget disease, inclusion body myopathy, and frontotemporal dementia is caused by a mutation in the gene that encodes valosin-containing protein.

Paget disease must be differentiated from primary bone lesions such as osteogenic sarcoma, multiple myeloma, and fibrous dysplasia and from secondary bone lesions such as metastatic carcinoma and osteitis fibrosa cystica. Fibrogenesis imperfecta ossium is a rare symmetric disorder that can mimic the features of Paget disease; alkaline phosphatase is likewise elevated. If serum calcium is elevated, hyperparathyroidism may be present in some patients as well.

Complications

If immobilization occurs, hypercalcemia and renal calculi may develop. Vertebral collapse may lead to spinal cord compression. The increased vascularity may give rise to high-output cardiac failure. Arthritis frequently develops in joints adjacent to involved bone.

Extensive skull involvement may cause cranial nerve palsies from impingement of the neural foramina. Involvement of the petrous temporal bone frequently causes hearing loss (mixed sensorineural and conductive) and occasionally tinnitus or vertigo. Vertebral involvement can cause compression of spinal nerves, resulting in radiculopathy or paralysis. The affected bones have a high blood flow and can thereby cause a vascular "steal" syndrome. Skull involvement can cause a vascular steal syndrome with somnolence or ischemic neurologic events; the optic nerve may be affected, resulting in loss of vision. Vertebral involvement can cause a vascular steal syndrome with paralysis. Jaw involvement can cause the teeth to spread intraorally and become misaligned.

Osteosarcoma may develop in long-standing lesions but is rare (< 1%). Sarcomatous change is suggested by a marked increase in bone pain, sudden rise in alkaline phosphatase, and appearance of a new lytic lesion.

Treatment

Asymptomatic patients may require only clinical surveillance and no treatment. However, treatment should be considered for asymptomatic patients who have extensive involvement of the skull, long bones, or vertebrae. Patients must be monitored carefully before, during, and after treatment with clinical examinations and serial serum alkaline phosphatase determinations.

Bisphosphonates

Bisphosphonates are the treatment of choice for Paget disease. Bisphosphonates are usually given cyclically. Therapy is given until a therapeutic response occurs, as evidenced by normalization of the serum alkaline phosphatase. After a course of therapy, patients are given a break for about 3 months or until the serum alkaline phosphatase begins rising again; another cycle is then commenced.

Patients frequently experience a paradoxical increase in pain soon after commencing bisphosphonate therapy; this is the "first dose effect" and the pain usually subsides with further treatment. Flu-like symptoms occur fairly frequently. Osteonecrosis, particularly of the jaw, is rare but can occur spontaneously or after tooth extraction.

The oral bisphosphonates should all be taken with 8 oz of plain water only; they are relatively contraindicated in patients with a history of esophagitis, esophageal stricture, dysphagia, hiatal hernia, or achalasia. **Alendronate**, 40 mg orally daily for 3–6 month cycles, must be taken in the morning with water only, at least 30-40 minutes before any other food, liquids, or medications. Patients should not lie down for at least 30 minutes after taking alendronate to reduce the risk of esophagitis. **Tiludronate**, 400 mg orally daily for 3-month cycles, should not be taken within 2 hours of meals, aspirin, indomethacin, calcium, magnesium, or aluminum-containing antacids. Esophagitis is uncommon, but it is still advisable to avoid recumbency for 30 minutes after dosing; but the drug may be taken in the evening as well as during the day. The most common side effects have been gastrointestinal, including abdominal pain in 13% and nausea in 9%. **Risedronate**, 30 mg orally daily for 2-month cycles, must be taken in the morning with water only, at least 30–40 minutes before any other food, liquids, or medications. Patients should not lie down for at least 30 minutes after taking risedronate to reduce the risk of esophagitis.

Parenteral bisphosphonates are particularly useful for patients who cannot tolerate oral bisphosphonates.

Intravenous bisphosphonates can produce clinical improvements that last several months. Serum alkaline phosphatase levels may continue to drop for 6 months after treatment. They appear to be more effective than oral bisphosphonates but have more systemic side effects. Postinfusion fever, fatigue, myalgia, bone pain, and ocular problems occur commonly and may sometimes be severe. Serious side effects are rare but include uveitis and acute kidney disease. Hypocalcemia is common and may be severe, especially if intravenous bisphosphonates are given along with loop diuretics. It is advisable to administer calcium and vitamin D supplements, especially during the first 2 weeks following treatment. Asthma may occur in aspirin-sensitive patients. **Pamidronate**, 30–60 mg is infused intravenously over 2–4 hours. Depending on the disease severity, one to three additional doses may be given days or weeks apart. **Zoledronic acid** can be given every 6–12 months in doses of 2–5 mg intravenously over 20 minutes. Six months following a single infusion of zoledronic acid, patients had a clinical response rate of 96%, compared with 74% in patients receiving daily oral risedronate. Intravenous zoledronic acid has been demonstrated to be significantly more effective than daily risedronate.

Nasal Calcitonin-Salmon

Miacalcin, 200 international units/unit dose spray, is administered as one spray daily, alternating nostrils. It is just as effective as the parenteral preparation and is associated with fewer side effects. Nasal irritation may occur, as may occasional epistaxis. Calcitonin has been used for many years to treat Paget disease. However, its use has declined dramatically with the introduction of more potent bisphosphonates.

Prognosis

The prognosis in general is good, but sarcomatous changes (in 1–3%) can alter it unfavorably. In general, the prognosis is worse the earlier in life the disease starts. Fractures usually heal well. In the severe forms, marked deformity, intractable pain, and cardiac failure are found. These complications should become rare with prompt bisphosphonate treatment.

Acute Adrenocortical Insufficiency (Adrenal Crisis)

Essentials of Diagnosis

- Weakness, abdominal pain, fever, confusion, nausea, vomiting, and diarrhea.
- Low blood pressure, dehydration; skin pigmentation may be increased.
- Serum potassium high, sodium low, BUN high.
- Cosyntropin ($ACTH_{1–24}$) unable to stimulate an increase in serum cortisol to 20 mcg/dL.

General Considerations

Acute adrenal insufficiency is an emergency caused by insufficient cortisol. Crisis may occur in the course of treatment of chronic insufficiency, or it may be the presenting manifestation of adrenal insufficiency. Acute adrenal crisis is more commonly seen in primary adrenal insufficiency (Addison disease) than in disorders of the pituitary gland causing secondary adrenocortical hypofunction.

Adrenal crisis may occur in the following situations: (1)

during stress, (eg, trauma, surgery, infection, hyperthyroidism, or prolonged fasting) in a patient with latent or treated adrenal insufficiency; (2) following sudden withdrawal of adrenocortical hormone in a patient with chronic insufficiency or in a patient with temporary insufficiency due to suppression by exogenous corticosteroids or megestrol (see illustration); (3) following bilateral adrenalectomy or removal of a functioning adrenal tumor that had suppressed the other adrenal; (4) following sudden destruction of the pituitary gland (pituitary necrosis), or when thyroid hormone is given to a patient with hypoadrenalism; and (5) following injury to both adrenals by trauma, hemorrhage, anticoagulant therapy, thrombosis, infection or, rarely, metastatic carcinoma; (6) following administration of etomidate, which is used intravenously for rapid anesthesia induction or intubation.

Hill Companies, Inc.)

Clinical Findings

Symptoms and Signs

The patient complains of headache, lassitude, nausea and vomiting, abdominal pain, and often diarrhea. Confusion or coma may be present. Fever may be 40.6 °C or more. The blood pressure is low. Recurrent hypoglycemia and reduced insulin requirements may present in patients with preexisting type 1 diabetes mellitus. Other signs may include cyanosis, dehydration, skin hyperpigmentation, and sparse axillary hair (if hypogonadism is also present). Meningococcemia may be associated with purpura and adrenal insufficiency secondary to adrenal infarction (Waterhouse–Friderichsen syndrome).

Laboratory Findings

The eosinophil count may be high. Hyponatremia or hyperkalemia (or both) are usually present. Hypoglycemia is frequent. Hypercalcemia may be present. Blood, sputum, or urine culture may be positive if bacterial infection is the precipitating cause of the crisis.

The diagnosis is made by a simplified cosyntropin stimulation test, which is performed as follows: (1) Synthetic ACTH$_{1–24}$ (cosyntropin), 0.25 mg, is given parenterally. (2) Serum is obtained for cortisol between

30 and 60 minutes after cosyntropin is administered. Normally, serum cortisol rises to at least 20 mcg/dL. For patients receiving corticosteroid treatment, hydrocortisone must not be given for at least 8 hours before the test. Other corticosteroids (eg, prednisone, dexamethasone) do not interfere with specific assays for cortisol.

Plasma ACTH is markedly elevated if the patient has primary adrenal disease (generally > 200 pg/mL).

Differential Diagnosis

Acute adrenal insufficiency must be distinguished from other causes of shock (eg, septic, hemorrhagic, cardiogenic). Hyperkalemia is also seen with gastrointestinal bleeding, rhabdomyolysis, hyperkalemic paralysis, and certain drugs (eg, angiotensin-converting enzyme [ACE] inhibitors, spironolactone). Hyponatremia is seen in many other conditions (eg, hypothyroidism, diuretic use, heart failure, cirrhosis, vomiting, diarrhea, severe illness, or major surgery). Acute adrenal insufficiency must be distinguished from an acute abdomen in which neutrophilia is the rule, whereas adrenal insufficiency is characterized by a relative lymphocytosis and eosinophilia.

More than 90% of serum cortisol is protein bound and low serum levels of binding proteins result in misleadingly low serum cortisol determinations by most assays. Nearly 40% of critically ill patients, with serum albumin < 2.5 g/dL, have low serum total cortisol levels but normal serum free cortisol or salivary cortisol levels and normal adrenal function.

Treatment

Acute Phase

If the diagnosis is suspected, draw a blood sample for cortisol determination and treat with hydrocortisone, 100–300 mg intravenously, and saline *immediately*, without waiting for the results. Thereafter, give hydrocortisone phosphate or hydrocortisone sodium succinate, 100 mg intravenously immediately, and continue intravenous infusions of 50–100 mg every 6 hours for the first day. Give the same amount every 8 hours on the second day and then adjust the dosage in view of the clinical picture.

Since bacterial infection frequently precipitates acute adrenal crisis, broad-spectrum antibiotics should be administered empirically while waiting for the results of initial cultures. Hypoglycemia should be vigorously treated while serum electrolytes, BUN, and creatinine are monitored.

Convalescent Phase

When the patient is able to take food by mouth, give oral hydrocortisone, 10–20 mg every 6 hours, and reduce dosage to maintenance levels as needed. Most patients ultimately require hydrocortisone twice daily (AM, 10–20 mg; PM, 5–10 mg). Mineralocorticoid therapy is not needed when large amounts of hydrocortisone are being given, but as the dose is reduced it is usually necessary to add fludrocortisone acetate, 0.05–0.2 mg daily. Some patients never require fludrocortisone or become edematous at doses of more than 0.05 mg once or twice weekly. Once the crisis has passed, the patient must be evaluated to assess the degree of permanent adrenal insufficiency and to establish the cause if possible.

Prognosis

Rapid treatment will usually be life-saving. However, acute adrenal insufficiency is frequently unrecognized and untreated since its manifestations mimic more common conditions; lack of treatment leads to shock that is unresponsive to volume replacement and vasopressors, resulting in death.

Lewandowsi KC et al. New onset Graves' disease as a cause of an adrenal crisis in an individual with panhypituitaris: brief report. Thyroid Res. 2008 Nov 19;1(1):7. [PMID: 19019235]

Lundy JB et al. Acute adrenal insufficiency after a single dose of etomidate. J Intensive Care Med. 2007 Mar–Apr;22(2):111–7. [PMID: 17456730]

Chronic Adrenocortical Insufficiency (Addison Disease)

Essentials of Diagnosis

- Weakness, fatigability, anorexia, weight loss; nausea and vomiting, diarrhea; abdominal pain, muscle and joint pains; amenorrhea.
- Sparse axillary hair; increased skin pigmentation, especially of creases, pressure areas, and nipples.
- Hypotension, small heart.
- Serum sodium may be low; potassium, calcium, and BUN may be elevated; neutropenia, mild anemia, eosinophilia, and relative lymphocytosis may be present.
- Plasma cortisol levels are low or fail to rise after administration of corticotropin.
- Plasma ACTH level is elevated.

General Considerations

Addison disease is an uncommon disorder caused by destruction or dysfunction of the adrenal cortices. It is characterized by chronic deficiency of cortisol, aldosterone, and adrenal androgens and causes skin pigmentation that can be subtle or strikingly dark. Volume and sodium depletion and potassium excess eventually occur in primary adrenal failure. In contrast, if chronic adrenal insufficiency is secondary to pituitary failure (atrophy, necrosis, tumor), mineralocorticoid production (controlled by the renin–angiotensin system) persists and hyperkalemia is not present. Furthermore, if ACTH is not elevated, skin pigmentary changes are not encountered.

Etiology

Autoimmune destruction of the adrenals is the most common cause of Addison disease in the United States (accounting for about 80% of spontaneous cases). With such autoimmunity, adrenal function decreases over several years as it progresses to overt adrenal insufficiency. It may occur alone or as part of a **polyglandular autoimmune (PGA) syndrome.** *Type 1 PGA* is also known as autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy (APCED) syndrome and is caused by a defect in T cell-mediated immunity inherited as an autosomal recessive trait. Type 1 PGA usually presents in early childhood with mucocutaneous candidiasis, followed by hypoparathyroidism and dystrophy of the teeth and nails; Addison disease usually appears by age 15 years. Partial or late expression of the syndrome is common. A varied spectrum of associated diseases may be seen in adulthood, including hypogonadism, hypothyroidism, pernicious anemia, alopecia, vitiligo, hepatitis, malabsorption, and Sjögren syndrome.

Type 2 PGA usually presents in young adults age 20–40 years, usually women (female:male ration is 3:1). The following conditions may be presentations of type 2 PGA: autoimmune adrenal insufficiency, type 1 diabetes mellitus, or autoimmune thyroid disease (usually hypothyroidism, sometimes hyperthyroidism). The combination of Addison disease and hypothyroidism is known as Schmidt syndrome. Patients may also have vitiligo, alopecia areata, Sjögren syndrome, or celiac sprue. Type 2 PGA is also associated with autoimmune primary ovarian failure; testicular failure (5%); pernicious anemia (4%); and, rarely, autoimmune hypophysitis, encephalitis, or hypoparathyroidism (late-onset).

Tuberculosis as a leading cause of Addison disease is relatively rare in the United States but common where tuberculosis is more prevalent.

Bilateral adrenal hemorrhage may occur during sepsis, heparin-associated thrombocytopenia or anticoagulation, or with antiphospholipid antibody syndrome. It may occur in association with major surgery or trauma, presenting about 1 week later with pain, fever, and shock. It may also occur spontaneously.

Adrenoleukodystrophy is an X-linked peroxisomal disorder causing accumulation of very long-chain fatty acids in the adrenal cortex, testes, brain, and spinal cord. It may present at any age and accounts for one-third of cases of Addison disease in boys. Aldosterone deficiency occurs in 9%. Hypogonadism is common. Psychiatric symptoms often include mania, psychosis, or cognitive impairment. Neurologic deterioration may be severe or mild (particularly in heterozygote women), mimics symptoms of multiple sclerosis, and can occur years after the onset of adrenal insufficiency.

Rare causes of adrenal insufficiency include lymphoma, metastatic carcinoma, coccidioidomycosis, histoplasmosis, cytomegalovirus infection (more frequent in patients with AIDS), syphilitic gummas, scleroderma, amyloid disease, and hemochromatosis.

Congenital adrenal insufficiency occurs in several conditions. **Familial glucocorticoid deficiency** is caused by a mutation in the gene encoding the adrenal ACTH receptor. **Triple A (Allgrove) syndrome** is characterized by variable expression of the following: adrenal ACTH resistance with cortisol deficiency, achalasia, alacrima, nasal voice, and neuromuscular disease of varying severity (hyperreflexia to spastic paraplegia). Cortisol deficiency usually presents in infancy but may not occur until the third decade of life. **Congenital adrenal hypoplasia** causes adrenal insufficiency due to absence of the adrenal cortex; patients may also have hypogonadotropic hypogonadism, myopathy, and high-frequency hearing loss. Patients with hereditary defects in adrenal enzymes for cortisol synthesis develop **congenital**

adrenal hyperplasia due to ACTH stimulation. The most common enzyme defect is P450c21 (21-hydroxylase). Patients with severely defective P450c21 enzymes manifest deficiency of mineralocorticoids (salt wasting) in addition to deficient cortisol and excessive androgens. Women with milder enzyme defects have adequate cortisol but develop hirsutism in adolescence or adulthood and are said to have "late-onset" congenital adrenal hyperplasia. (See Hirsutism section.)

Clinical Findings

Symptoms and Signs

The symptoms may include weakness and fatigability, weight loss, myalgias, arthralgias, fever, anorexia, nausea and vomiting, anxiety, and mental irritability. Some of these symptoms may be due to high serum levels of IL-6. Pigmentary changes consist of diffuse tanning over nonexposed as well as exposed parts or multiple freckles; hyperpigmentation is especially prominent over the knuckles, elbows, knees, and posterior neck and in palmar creases. Nail beds may develop longitudinal pigmented bands. Nipples and areolas tend to darken. The skin in pressure areas such as the belt or brassiere lines and the buttocks also darkens. New scars are pigmented. Some patients have associated vitiligo (10%). Emotional changes are common. Hypoglycemia, when present, may worsen the patient's weakness and mental functioning, rarely leading to coma. Manifestations of other autoimmune disease (see above) may be present. Patients tend to be hypotensive and orthostatic; about 90% have systolic blood pressures under 110 mm Hg; blood pressure over 130 mm Hg is rare. Other findings may include a small heart, hyperplasia of lymphoid tissues, and scant axillary and pubic hair (especially in women).

Patients with adult-onset adrenoleukodystrophy may present with neuropsychiatric symptoms, sometimes without adrenal insufficiency.

Laboratory Findings

The WBC count usually shows moderate neutropenia, lymphocytosis, and a total eosinophil count over 300/mcL. Among patients with *chronic* Addison disease, the serum sodium is usually low (90%) while the potassium is elevated (65%). Patients with diarrhea may not be hyperkalemic. Fasting blood glucose may be low. Hypercalcemia may be present. Young men with idiopathic Addison disease are screened for adrenoleukodystrophy by determining plasma very long-chain fatty acid levels; affected patients have high levels.

Low plasma cortisol (< 3 mcg/dL) at 8 AM is diagnostic, especially if accompanied by simultaneous elevation of the plasma ACTH level (usually > 200 pg/mL). The diagnosis is made by a simplified cosyntropin stimulation test, which is performed as follows: (1) Synthetic $ACTH_{1-24}$ (cosyntropin), 0.25 mg, is given parenterally. (2) Serum is obtained for cortisol between 30 and 60 minutes after cosyntropin is administered. Normally, serum cortisol rises to at least 20 mcg/dL. For patients receiving corticosteroid treatment, hydrocortisone must not be given for at least 8 hours before the test. Other corticosteroids (eg, prednisone, dexamethasone) do not interfere with specific assays for cortisol.

Serum DHEA levels are under 1000 ng/mL in 100% of patients with Addison disease and a serum DHEA above 1000 ng/mL excludes the diagnosis. However, serum DHEA levels below 1000 ng/mL are not helpful, since about 15% of the general population have such low DHEA levels, particularly children and elderly individuals. Antiadrenal antibodies are found in the serum in about 50% of cases of autoimmune Addison disease. Antibodies to thyroid (45%) and other tissues may be present.

Elevated plasma renin activity (PRA) indicates the presence of depleted intravascular volume and the need for higher doses of fludrocortisone replacement. Serum epinephrine levels are low in patients with adrenal insufficiency, since these patients do not have the high local concentrations of cortisol that are required to induce the enzyme PNMT in adrenal medulla for the synthesis of epinephrine from norepinephrine.

Imaging

When Addison disease is not clearly autoimmune, a chest radiograph is obtained to look for tuberculosis, fungal infection, or cancer as possible causes. CT scan of the abdomen will show small noncalcified adrenals in autoimmune Addison disease. The adrenals are enlarged in about 85% of cases due to metastatic or granulomatous disease. Calcification is noted in about 50% of cases of tuberculous Addison disease but is also seen with hemorrhage, fungal infection, pheochromocytoma, and melanoma.

Differential Diagnosis

Addison disease should be considered in any patient with unexplained hypotension, but shock is usually caused by more common conditions such as gastrointestinal bleeding or sepsis. Hyponatremia or hyperkalemia may be seen in numerous other conditions (see Chapter 21: Fluid & Electrolyte Disorders). Drospirenone, the progestin component in certain oral contraceptives, may cause hyperkalemia.

Unexplained weight loss, weakness, and anorexia may be mistaken for occult cancer. Nausea, vomiting, diarrhea, and abdominal pain may be misdiagnosed as intrinsic gastrointestinal disease. The hyperpigmentation may be confused with that due to ethnic or racial factors. Weight loss may simulate anorexia nervosa. The neurologic manifestations of Allgrove syndrome and adrenoleukodystrophy (especially in women) may mimic multiple sclerosis. Hemochromatosis also enters the differential diagnosis of skin hyperpigmentation, but it should be remembered that it may truly be a cause of Addison disease as well as diabetes mellitus and hypoparathyroidism. Serum ferritin is increased in most cases of hemochromatosis and is a useful screening test. About 17% of patients with AIDS have symptoms of cortisol resistance. AIDS can also cause frank adrenal insufficiency.

Hyperkalemia can be caused by isolated hypoaldosteronism and is seen in various conditions. Hyporeninemic hypoaldosteronism can be caused by renal tubular acidosis type IV and is commonly seen with diabetic nephropathy, hypertensive nephrosclerosis, tubulointerstitial diseases, and AIDS; hyperkalemia, hyperchloremia, and metabolic acidosis (see Chapter 21: Fluid & Electrolyte Disorders) are presenting signs. Hyperreninemic hypoaldosteronism can be seen in patients with myotonic dystrophy, aldosterone synthase deficiency, and congenital adrenal hyperplasia. Hyperkalemia, hypertension, and hypogonadism may present as delayed adolescence or in adulthood in some patients with congenital adrenal hyperplasia (CYP17 deficiency); cortisol deficiency is also usually present but may not be clinically evident.

Complications

Any of the complications of the underlying disease (eg, tuberculosis) are more likely to occur, and the patient is susceptible to intercurrent infections that may precipitate crisis. Associated autoimmune diseases are common (see above).

Treatment

Specific Therapy

Replacement therapy should include a combination of corticosteroids and mineralocorticoids. In mild cases, hydrocortisone alone may be adequate.

Hydrocortisone is the drug of choice. Most addisonian patients are well maintained on 15–30 mg of hydrocortisone orally daily in two divided doses, two-thirds in the morning and one-third in the late afternoon or early evening. Some patients respond better to prednisone in a dosage of about 2–4 mg in the morning and 1–2 mg in the evening. Adjustments in dosage are made according to the clinical response. A proper dose usually results in a normal differential WBC count.

Fludrocortisone acetate has a potent sodium-retaining effect. The dosage is 0.05–0.3 mg orally daily or every other day. In the presence of postural hypotension, hyponatremia, or hyperkalemia, the dosage is increased. Similarly, in patients with fatigue, elevated PRA indicates the need for a higher replacement dose of fludrocortisone. If edema, hypokalemia, or hypertension ensues, the dose is decreased.

DHEA is given to some patients with adrenal insufficiency. In a double-blind clinical trial, patients taking DHEA 50 mg orally each morning have experienced an improvement in their overall sense of well-being, an increase in muscle mass, and a reversal in bone loss at the femoral neck. DHEA replacement did not improve fatigue or sexual dysfunction; however, its placebo effect may be significant in that regard. Older women who receive DHEA should be monitored for androgenic effects. Because over-the-counter preparations of DHEA have variable potencies, it is best to have the pharmacy formulate this with pharmaceutical-grade micronized DHEA.

General Measures

Patients with Addison disease must be thoroughly informed about their condition. All infections should be treated immediately and vigorously, with the dose of hydrocortisone increased appropriately. The dose of corticosteroid should also be raised in case of trauma, surgery, stressful diagnostic procedures, or other forms of stress. The maximum hydrocortisone dose for severe stress is 50 mg intravenously or intramuscularly every 6 hours. Lower doses, oral or parenteral, are used for less severe stress. The dose is reduced back to normal as the stress subsides. Patients are advised to wear a medical alert bracelet or medal reading, "Adrenal insufficiency—takes hydrocortisone."

Prognosis

The life expectancy of patients with Addison disease has been considered reasonably normal, as long as they are very compliant with taking their medications and are knowledgeable about their condition. However, a retrospective Swedish study of 1675 patients with Addison disease found an unexpected increase in all-cause mortality, mostly from cardiovascular disease, malignancy, and infectious causes. Associated conditions can pose additional health risks. For example, patients with adrenoleukodystrophy or Allgrove syndrome may suffer from neurologic disease. Patients with adrenal tuberculosis may have a serious systemic infection that requires treatment. Adrenal crisis can occur in patients who stop their medication or who experience stress such as infection, trauma, or surgery without appropriately higher doses of corticosteroids. Patients who take excessive doses of corticosteroid replacement can develop

Cushing syndrome, which imposes its own risks.

Many patients with treated Addison disease complain of chronic low-grade fatigue.

Many patients with Addison disease do not feel entirely normal, despite glucocorticoid and mineralocorticoid replacement. This may be due, in part, to the inadequacy of oral replacement to duplicate cortisol's normal circadian rhythm. Also, patients with Addison disease are deficient in epinephrine, but replacement epinephrine is not available. Fatigue may also be an indication of suboptimal dosing of medication, electrolyte imbalance, or concurrent problems such as hypothyroidism or diabetes mellitus. However, most patients with Addison disease are able to live fully active lives.

Cushing Syndrome (Hypercortisolism)

Essentials of Diagnosis

- Central obesity, muscle wasting, thin skin, hirsutism, purple striae.
- Psychological changes.
- Osteoporosis, hypertension, poor wound healing.
- Hyperglycemia, glycosuria, leukocytosis, lymphocytopenia, hypokalemia.
- Elevated serum cortisol and urinary free cortisol. Lack of normal suppression by dexamethasone.

General Considerations

The term Cushing "syndrome" refers to the manifestations of excessive corticosteroids, commonly due to supraphysiologic doses of corticosteroid drugs and rarely due to spontaneous production of excessive corticosteroids by the adrenal cortex. Cases of spontaneous Cushing syndrome are rare (2.6 new cases yearly per million population) and have several possible causes.

About 40% of cases are due to Cushing "disease," by which is meant the manifestations of hypercortisolism due to ACTH hypersecretion by the pituitary. Cushing disease is caused by a benign pituitary adenoma that is typically very small (< 5 mm) and usually located in the anterior pituitary (98%) or in the posterior pituitary (2%). It is at least three times more frequent in women than men.

About 10% of cases are due to nonpituitary ACTH-secreting neoplasms (eg, small cell lung carcinoma), which produce excessive amounts of ectopic ACTH. Hypokalemia and hyperpigmentation are commonly found in this group.

About 15% of cases are due to ACTH from a source that cannot be initially located.

About 30% of cases are due to excessive autonomous secretion of cortisol by the adrenals—independently of ACTH, serum levels of which are usually low. Most such cases are due to a unilateral adrenal tumor: Benign adrenal adenomas are generally small and produce mostly cortisol; adrenal carcinomas are usually large when discovered and can produce excessive cortisol as well as androgens, with resultant hirsutism and virilization. ACTH-independent macronodular adrenal hyperplasia can also produce hypercortisolism due to the adrenal cortex cells' abnormal stimulation by hormones such as catecholamines, argininevasopressin, serotonin, hCG/LH, or gastric inhibitory polypeptide; in the latter case, hypercortisolism may be intermittent and food dependent and serum ACTH may not be completely suppressed. Pigmented bilateral adrenal macronodular adrenal hyperplasia is a rare cause of Cushing syndrome in children and young adults; it may be an isolated condition or part of the Carney complex.

Clinical Findings

Symptoms and Signs

Patients with Cushing syndrome usually have central obesity with a plethoric "moon face," "buffalo hump," supraclavicular fat pads, protuberant abdomen, and thin extremities; oligomenorrhea or amenorrhea (or impotence in the male); weakness, backache, and headache; hypertension; osteoporosis; avascular bone necrosis; and acne and superficial skin infections (see illustration). Patients may have thirst and polyuria (with or without glycosuria), renal calculi, glaucoma, purple striae (see photograph) (especially around the thighs, breasts, and abdomen), and easy bruisability. Wound healing is impaired. Mental symptoms may range from diminished ability to concentrate to increased lability of mood to frank psychosis. Patients are susceptible to opportunistic infections.

Fig.

Axillary pigmented striae of Cushing syndrome preoperatively. (Courtesy of C Grunfeld.)

Laboratory Findings

Glucose tolerance is impaired as a result of insulin resistance. Polyuria is present as a result of increased free water clearance; diabetes mellitus with glycosuria may worsen it. Patients with Cushing syndrome often have leukocytosis with relative granulocytosis and lymphopenia. Hypokalemia may be present, particularly in cases of ectopic ACTH secretion.

Tests for Hypercortisolism

The easiest screening test for Cushing syndrome is the dexamethasone suppression test: dexamethasone 1 mg is given orally at 11 pm and serum is collected for cortisol determination at about 8 am the next morning; a cortisol level under 5 mcg/dL (< 135 nmol/L, fluorometric assay) or under 2 mcg/dL (< 54 nmol/L, high-performance liquid chromatography [HPLC] assay) excludes Cushing syndrome with some certainty. However, 8% of established patients with pituitary Cushing disease have dexamethasone-suppressed cortisol levels < 2 mcg/dL. Therefore, when other clinical criteria suggest hypercortisolism, further evaluation is warranted even in the face of normal dexamethasone-suppressed serum cortisol. Antiseizure drugs (eg, phenytoin, phenobarbital, primidone) and rifampin accelerate the metabolism of dexamethasone, in that way causing a lack of cortisol suppression by dexamethasone. Estrogens—during pregnancy or as oral contraceptives or ERT—may also cause lack of dexamethasone suppressibility.

Patients with an abnormal dexamethasone suppression test require further investigation, which includes a 24-hour urine collection for free cortisol and creatinine. An abnormally high 24-hour urine free cortisol (or free cortisol to creatinine ratio of > 95 mcg cortisol/g creatinine) helps confirm hypercortisolism. A misleadingly high urine free cortisol excretion occurs with high fluid intake. In pregnancy, urine free cortisol is increased, while 17-hydroxycorticosteroids remain normal and diurnal variability of serum cortisol is normal. Carbamazepine and fenofibrate cause false elevations of urine free cortisol when determined by HPLC.

A midnight serum cortisol level > 7.5 mcg/dL is indicative of Cushing syndrome and distinguishes it from other conditions associated with a high urine free cortisol (pseudo-Cushing states; see Differential Diagnosis, below). Requirements for this test include being in the same time zone for at least 3 days, being without food for at least 3 hours, and having an indwelling intravenous line established in advance for the blood draw.

Due to the inconvenience of obtaining a midnight blood specimen for serum cortisol, late-night salivary cortisol assays have proved useful. Salivary cortisol kits can be ordered at www.acllaboratories.com. A standardized enzyme-linked immunosorbent assay (ELISA) is used by reliable laboratories. Using ELISA, midnight salivary cortisol levels are normally < 0.15 mcg/dL (4.0 nmol/L). Midnight salivary cortisol levels that are consistently > 0.25 mcg/dL (7.0 nmol/L) are considered very abnormal. The late-night salivary cortisol test has a high sensitivity and specificity for Cushing syndrome, but false-positive and false-negative tests have occurred.

Interestingly, hypercortisolism without Cushing syndrome can occur in several conditions, such as severe depression, anorexia nervosa, alcoholism, and familial cortisol resistance. (See Differential Diagnosis, below.)

Finding the Cause of Hypercortisolism

Once hypercortisolism is confirmed, a plasma or serum ACTH is obtained. It must be collected properly in a plastic tube on ice and processed quickly by a laboratory with a reliable, sensitive assay. A level of ACTH below about 20 pg/mL indicates a probable adrenal tumor, whereas higher levels are produced by pituitary or ectopic ACTH-secreting tumors.

Localizing Techniques

In ACTH-dependent Cushing syndrome, MRI of the pituitary demonstrates a pituitary lesion in about 50% of cases. Premature cerebral atrophy is often noted. When the pituitary MRI is normal or shows a tiny (< 5 mm diameter) irregularity that may be incidental, selective catheterization of the inferior petrosal sinus veins draining the pituitary is performed. ACTH levels in the inferior petrosal sinus that are more than twice the simultaneous peripheral venous ACTH levels are indicative of pituitary Cushing disease. Inferior petrosal sinus sampling is also done during CRH administration, which ordinarily causes the ACTH levels in the inferior petrosal sinus to be over three times the peripheral ACTH level when the pituitary is the source of ACTH.

When inferior petrosal sinus ACTH concentrations are not above the requisite levels, a search for an ectopic source of ACTH is undertaken. Location of ectopic sources of ACTH commences with CT scanning of the chest and abdomen, with special attention to the lungs (for carcinoid or small cell carcinomas), the thymus, the pancreas, and the adrenals. In patients with ACTH-dependent Cushing syndrome, chest masses should not be assumed to be the source of ACTH, since opportunistic infections are common, so it is prudent to biopsy a chest mass to confirm the pathologic diagnosis prior to resection.

CT scanning fails to detect the source of ACTH in about 40% of patients with ectopic ACTH secretion. ^{111}In-octreotide (OCT, somatostatin receptor scintigraphy) scanning is also useful in detecting occult tumors. A low-dose scan with 6 mCi $^{\mathrm{OCT}}$ is used first; a high-dose scan with 12 mCi $^{\mathrm{OCT}}$ may be used if the low-dose scan gives equivocal results. ^{18}FDG-PET scanning is not usually helpful. Some ectopic ACTH-secreting tumors elude discovery, necessitating bilateral adrenalectomy. The ectopic source of ACTH should continue to be sought, since they may become detectable by OCT or CT scanning at a later date.

In non-ACTH-dependent Cushing syndrome, a CT scan of the adrenals can localize the adrenal tumor in most cases (see CT scan).

Fig.

Adrenal CT scans in Cushing syndrome. ***A:*** Patient with ACTH-dependent Cushing syndrome. The adrenal glands are not detectably abnormal by this procedure. The curvilinear right adrenal *(black arrow)* is shown posterior to the inferior vena cava (v) between the right lobe of the liver and the right crus of the diaphragm. The left adrenal *(white arrow)* has an inverted Y appearance anteromedial to the left kidney (k). ***B:*** A 3-cm left adrenal adenoma *(white arrow)* is shown anteromedial to the left kidney (k). (Reproduced, with permission, from Korobkin MT et al: Computed tomography in the diagnosis of adrenal disease. Am J Roentgenol 1979;132:231.)

Differential Diagnosis

Alcoholic patients can have hypercortisolism and many clinical manifestations of Cushing syndrome. Regular use of the "party drug" gamma hydroxybutyrate (GHB, sodium oxybate) has been reported to cause reversible ACTH-dependent Cushing syndrome. Depressed patients also have hypercortisolism that can be nearly impossible to distinguish biochemically from Cushing syndrome but without clinical signs of Cushing syndrome. Some adolescents develop violaceous striae on the abdomen, back, and breasts; these are known as "striae distensae" and are not indicative of Cushing syndrome. Cushing syndrome can be misdiagnosed as anorexia nervosa (and vice versa) owing to the muscle wasting and extraordinarily high urine free cortisol levels found in anorexia. Patients with severe obesity frequently have an abnormal dexamethasone suppression test, but the urine free cortisol is usually normal, as is diurnal variation of serum cortisol. Patients with familial cortisol resistance have hyperandrogenism, hypertension, and hypercortisolism without actual Cushing syndrome. In patients with familial partial lipodystrophy type I, central obesity and a moon facies develop, along with thin extremities due to atrophy of subcutaneous fat. However, these patients' muscles are strong and may be hypertrophic, distinguishing this condition from Cushing syndrome. Patients receiving antiretroviral therapy for HIV-1 infection frequently develop partial lipodystrophy with thin extremities and central obesity with a dorsocervical fat pad ("buffalo hump") that may mimic Cushing syndrome.

Complications

Cushing syndrome, if untreated, produces serious morbidity and even death. The patient may suffer from any of the complications of hypertension or of diabetes. Susceptibility to infections is increased. Compression fractures of the osteoporotic spine and aseptic necrosis of the femoral head may cause marked disability. Nephrolithiasis and psychosis may occur. Following bilateral adrenalectomy for Cushing disease, a pituitary adenoma may enlarge progressively, causing local destruction (eg, visual field impairment) and hyperpigmentation; this complication is known as Nelson syndrome.

Treatment

Cushing disease is best treated by transsphenoidal selective resection of the pituitary adenoma. After pituitary surgery, the rest of the pituitary usually returns to normal function; however, the pituitary corticotrophs remain suppressed and require 6–36 months to recover normal function. Hydrocortisone or prednisone replacement therapy is necessary in the meantime. Patients who do not have a remission (or who have a recurrence) should be treated by bilateral laparoscopic adrenalectomy. Another treatment option for patients with ACTH-secreting pituitary tumors is stereotactic pituitary radiosurgery (gamma knife or cyberknife), which normalizes urine free cortisol in two-thirds of patients within 12 months. Conventional radiation therapy results in a 23% cure rate.

Pituitary radiosurgery can also be used to treat Nelson syndrome, the progressive enlargement of ACTH-secreting pituitary tumors following bilateral adrenalectomy. Patients who are not surgical candidates may be given a trial of ketoconazole in doses of about 200 mg every 6 hours; liver enzymes must be monitored for progressive elevation.

Adrenal neoplasms secreting cortisol are resected laparoscopically. The contralateral adrenal is suppressed, so postoperative hydrocortisone replacement is required until recovery occurs. Metastatic adrenal carcinomas may be treated with mitotane; ketoconazole or metyrapone can help suppress hypercortisolism in unresectable adrenal carcinoma. The thiazolidinedione rosiglitazone has slowed the growth of adrenal carcinomas in-vitro, but clinical trials are lacking.

Ectopic ACTH-secreting tumors should be located, when possible, and surgically resected. If that cannot be done, laparascopic bilateral adrenalectomy is recommended. Medical treatment with ketoconazole or metyrapone (or both) may partially suppress the hypercortisolism; however, metyrapone may exacerbate female virilization. The somatostatin analog octreotide, given parenterally, suppresses ACTH secretion in about one-third of such cases.

Patients who are successfully treated for Cushing syndrome typically develop "cortisol withdrawal syndrome," even when given replacement corticosteroids for adrenal insufficiency. Manifestations can include hypotension, nausea, fatigue, arthralgias, myalgias, pruritus, and flaking skin. Increasing the hydrocortisone replacement to 30 mg twice daily can improve these symptoms; the dosage is then reduced as tolerated.

Prognosis

Patients with Cushing syndrome from a benign adrenal adenoma experience a 5-year survival of 95% and a 10-year survival of 90%, following a successful adrenalectomy. Patients with Cushing disease from a pituitary adenoma experience a similar survival if their pituitary surgery is successful. However, transsphenoidal surgery incurs a failure rate of about 10–20%, often due to the adenoma's ectopic position or invasion of the cavernous sinus. Those patients who have a complete remission after transsphenoidal surgery have about a 15–20% chance of recurrence over the next 10 years. Patients with failed pituitary surgery may require pituitary radiation therapy, which has its own morbidity. Bilateral adrenalectomy is often complicated by infection; recurrence of hypercortisolism may occur as a result of growth of an adrenal remnant stimulated by high levels of ACTH. The prognosis for patients with ectopic ACTH-producing tumors depends on the aggressiveness and stage of the particular tumor. Patients with ACTH of unknown source have a 5-year survival rate of 65% and a 10-year survival rate of 55%. Patients with adrenal carcinoma have a median survival of 7 months.

Hirsutism & Virilization

Essentials of Diagnosis

- Hirsutism, acne, menstrual disorders.
- Virilization: increased muscularity, androgenic alopecia, deepening of the voice, clitoromegaly.
- Rarely, a palpable pelvic tumor.
- Urinary 17-ketosteroids and serum DHEAS and androstenedione elevated in adrenal disorders; variable in others.

- Serum testosterone is often elevated.

General Considerations

Hirsutism is defined as excessive terminal hair growth that appears in a male pattern in women. Hirsutism is frequently quantitated according to the Ferriman-Gallwey scale, which grades the presence of androgen sensitive hair from 0 (no hair) to 4 (virile) in 9 areas of the body (maximum score = 36). About 5% of reproductive age women are hisute, with Ferriman-Gallwey scores 8.

Etiology

Hirsutism may be idiopathic or familial or be caused by the following disorders: polycystic ovary syndrome (PCOS), steroidogenic enzyme defects, neoplastic disorders or rarely by medications, acromegaly, or ACTH-induced Cushing disease.

Idiopathic or Familial

Most women with hirsutism or androgenic alopecia have no detectable hyperandrogenism. Patients often have a strong familial predisposition to hirsutism that may be considered normal in the context of their genetic background. Such patients may have elevated serum levels of androstenediol glucuronide, a metabolite of dihydrotestosterone that is produced by skin in cosmetically unacceptable amounts.

Polycystic Ovary Syndrome (Hyperthecosis, Stein–Leventhal Syndrome)

PCOS is a common functional disorder of the ovaries, affecting about 4–6% of premenopausal women in the United States and accounting for at least 50% of all cases of hirsutism associated with elevated testosterone levels. It is familial and transmitted as a modified autosomal dominant trait. Affected women have elevated serum testosterone or free testosterone levels. Affected women have signs of androgen excess, including hirsutism, acne, and male-pattern thinning of scalp hair. About 50% of affected women have oligomenorrhea or amenorrhea with anovulation. Despite the syndrome's name, the presence of ovarian cysts is not helpful diagnostically, since about 30% of women with PCOS do *not* have cystic ovaries and 25–30% of normal menstruating women *have* cystic ovaries. Obesity and high serum insulin levels (due to insulin resistance) contribute to the syndrome in 70% of women. The serum LH:FSH ratio is often greater than 2.0. Both adrenal and ovarian androgen hypersecretion are commonly present. Women with PCOS have a 35% risk of depression, compared with 11% in age-matched controls. Diabetes mellitus is present in about 13% of cases. Untreated women with amenorrhea have a slightly increased risk of endometrial carcinoma. Hypertension and hyperlipidemia are often present, increasing the risk of cardiovascular disease. Women frequently regain normal menstrual cycles with aging.

Steroidogenic Enzyme Defects

Baby girls with "classic" 21-hydroxylase deficiency have ambiguous genitalia and may become virilized unless treated with corticosteroid replacement; about 50% of such patients have clinically evident mineralocorticoid deficiency (salt-wasting) as well.

About 2% of patients with adult-onset hirsutism have been found to have a partial defect in adrenal 21-hydroxylase, whose phenotypic expression is delayed until adolescence or adulthood; such patients do not have salt-wasting. Polycystic ovaries and adrenal adenomas are more likely to develop in these women.

Some rare patients with hyperandrogenism and hypertension have 11-hydroxylase deficiency. This is distinguished from cortisol resistance by high cortisol serum levels in the latter and by high serum 11-deoxycortisol levels in the former.

Patients with an XY karyotype and a deficiency in 17 -hydroxysteroid dehydrogenase-3 or a deficiency in 5 -reductase-2 may present as phenotypic girls in whom virilization develops at puberty.

Neoplastic Disorders

Ovarian tumors are very uncommon causes of hirsutism (0.8%) and include arrhenoblastomas, Sertoli-Leydig cell tumors, dysgerminomas, and hilar cell tumors. Adrenal carcinoma is a rare cause of Cushing syndrome and hyperandrogenism that can be quite virilizing. Pure androgen-secreting adrenal tumors occur very rarely; about 50% are malignant.

Rare Causes of Hirsutism

Acromegaly and ACTH-induced Cushing syndrome can cause hirsutism. Maternal virilization during pregnancy may occur as a result of a luteoma of pregnancy, hyperreactio luteinalis, or polycystic ovaries. In postmenopausal women, diffuse stromal Leydig cell hyperplasia is a rare cause of hyperandrogenism. Aquired hypertrichosis lanuginosa is manifested by the appearance of diffuse fine lanugo hair growth on the face and body along with stomatologic symptoms; the disorder is usually associated with an internal malignancy, especially colorectal cancer, and may regress after tumor removal. Pharmacologic causes include minoxidil, cyclosporine, phenytoin, anabolic steroids, diazoxide, and certain progestins.

Clinical Findings

Symptoms and Signs

Modest androgen excess from any source increases sexual hair (chin, upper lip, abdomen, and chest) and increases sebaceous gland activity, producing acne. Menstrual irregularities, anovulation, and amenorrhea are common. If androgen excess is pronounced, defeminization (decrease in breast size, loss of feminine adipose tissue) and virilization (frontal balding, muscularity, clitoromegaly, and deepening of the voice) occur. Virilization implicates the presence of an androgen-producing neoplasm.

Hypertension may be seen in rare patients with Cushing syndrome, adrenal 11-hydroxylase deficiency, or cortisol resistance syndrome.

A pelvic examination may disclose clitoromegaly or ovarian enlargement that may be cystic or neoplastic.

Laboratory Testing and Imaging

Serum androgen testing is mainly useful to screen for rare occult adrenal or ovarian neoplasms. Some general guidelines are presented here, though exceptions are common.

Serum is assayed for total testosterone and free testosterone. A serum testosterone level > 200 ng/dL or free testosterone > 40 ng/dL indicates the need for pelvic examination and ultrasound. If that is negative, an adrenal CT scan is performed.

Most radioimmunoassays and ELISA for testosterone are inaccurate below serum testosterone levels of 300 ng/dL. The more accurate testosterone assays rely upon extraction and chromatography, followed by mass spectrometry or immunoassay. Free testosterone is best measured by calculation, using accurate assays for testosterone and SHBG.

A serum androstenedione level > 1000 ng/dL also implicates an ovarian or adrenal neoplasm.

Patients with milder elevations of serum testosterone or androstenedione usually are treated with an oral contraceptive.

Patients with very elevated serum DHEAS (> 700 mcg/dL) have an adrenal source of androgen. This usually is due to adrenal hyperplasia and rarely to adrenal carcinoma. An adrenal CT scan is performed.

No firm guidelines exist as to which patients (if any) with hyperandrogenism should be screened for "late-onset" 21-hydroxylase deficiency. The evaluation requires levels of serum 17-hydroxyprogesterone to be drawn at baseline and at 30–60 minutes after the intramuscular injection of 0.25 mg of cosyntropin ($ACTH_{1–24}$). This test should ideally be done during the follicular phase of a woman's menstrual cycle. Patients with congenital adrenal hyperplasia will usually have a baseline 17-

hydroxyprogesterone level over 300 ng/dL or a stimulated level over 1000 ng/dL. The diagnosis, once made, is interesting academically but not helpful to the patient since corticosteroid treatment is not particularly more effective in this condition than are other treatment modalities (see below).

Patients with any clinical signs of Cushing syndrome should receive a screening test. (See Cushing Syndrome.)

Serum levels of FSH and LH are elevated if amenorrhea is due to ovarian failure. An LH:FSH ratio greater than 2.0 is common in patients with PCOS. On abdominal ultrasound, about 25–30% of normal young women have polycystic ovaries, so the appearance of ovarian cysts on ultrasound is not helpful. So, the "polycystic" ovary syndrome is actually a misnomer and the diagnosic criteria for PCOS does not include imaging evidence of polycystic ovaries.

Virilizing tumors of the ovary can usually be detected by pelvic ultrasound or MRI. However, small virilizing ovarian tumors may not be detectable on imaging studies; selective venous sampling for testosterone may be used for diagnosis in such patients.

Treatment

Postmenopausal women with severe hyperandrogenism should undergo laparoscopic bilateral oophorectomy (if

CT scan of the adrenals and ovaries is normal), since small hilar cell tumors of the ovary may not be visible on scans. Girls with hyperandrogenism due to classic salt-wasting congenital adrenal hyperplasia may be treated with laparoscopic bilateral adrenalectomy. Any drugs causing hirsutism are stopped.

Spironolactone may be taken in doses of 50–100 mg orally twice daily on days 5–25 of the menstrual cycle or daily if used concomitantly with an oral contraceptive. Hyperkalemia or hyponatremia is uncommon.

Cyproterone acetate is a potent antiandrogen with progestational activity. A dose of 2 mg orally is effective. An oral contraceptive is usually prescribed also. Cyproterone is not available in the United States but is available elsewhere as the progestin element in an oral contraceptive (Diane-35: ethinyl estradiol 35 mcg with cyproterone acetate 2 mg). Side effects may include fatigue, nausea, depression, or hyperlipidemia.

Finasteride inhibits 5 -reductase, the enzyme that converts testosterone to active dihydrotestosterone in the skin. Given as 2.5-mg doses orally daily, it provides modest reduction in hirsutism over 6 months—somewhat less than that achieved with spironolactone. Finasteride is ineffective for androgenic alopecia in women. Side effects are rare.

Flutamide inhibits androgen reception uptake and also suppresses serum androgen. It is given orally in a dosage of 250 mg/d for the first year and then 125 mg/d for maintenance. Used with an oral contraceptive, it appears to be more effective than spironolactone in improving hirsutism, acne, and male pattern baldness. Women with congenital adrenal hyperplasia who take replacement hydrocortisone, experience decreased renal cortisol clearance when treated with flutamide, resulting in lower hydrocortisone dosage requirements; corticosteroid replacement doses should be reduced when flutamide is added for treatment of hirsutism. Hepatotoxicity has been reported but is rare.

Oral contraceptives stimulate menses (if that is desired) and reduce acne vulgaris, but are less effective for hirsutism. Contraceptives containing antiandrogen progestins (either desogestrel 0.15 mg or levonorgestrel 0.15 mg) may be more effective for treating hirsutism but are associated with an increased risk of deep venous thrombosis. Simvastatin, when added to oral contraceptive therapy, has been reported to further decrease serum free testosterone by 16%, besides improving patients' serum lipid profiles.

Metformin may improve menstrual function in women with PCOS and amenorrhea or oligomenorrhea, but is less effective than oral contraceptives. Metformin is not effective in promoting fertility or in improving hirsutism in women with PCOS. Metformin therapy is usually given with meals and is started at a dose of 500 mg/d with breakfast for 1 week, then 500 mg with breakfast and dinner for 1 week, then 500 mg with breakfast and 1000 mg with dinner for 1 week, then 1000 mg with breakfast and dinner. The most common side effects are dose-related gastrointestinal upset and diarrhea. Patients are advised to take the highest tolerated dosage. Metformin appears to be nonteratogenic. Although metformin reduces insulin resistance, it does not cause hypoglycemia in nondiabetics. Metformin is contraindicated in renal and hepatic disease.

Clomiphene is the treatment of choice for women with PCOS and infertility. Over 6 months, clomiphene therapy resulted in a 22.5% rate of conception with live births. The rate of pregnancy with multiple fetuses is 6%.

Women with classic congenital adrenal hyperplasia (21-hydroxylase deficiency) have hirsutism and adrenal insufficiency that requires glucocorticoid and mineralocorticoid replacement. However, women with partial "late onset" 21-hydroxylase deficiency do not require hormone replacement. Treating such women with dexamethasone risks iatrogenic Cushing syndrome and is not particularly more effective than the other treatments for hirsutism listed in this section.

Local treatment by shaving or depilatories, waxing, electrolysis, or bleaching should be encouraged. Eflornithine (Vaniqua 13.9%) topical cream retards hair growth when applied twice daily to unwanted facial hair; improvement is noted within 4–8 weeks. However, local skin irritation may occur. Hirsutism returns with discontinuation. Laser therapy (photoepilation) is an effective treatment for facial hirsutism, particularly for women with dark hair and light skin; complications include skin hypopigmentation (rare) and hyperpigmentation, which occurs in 20% but usually resolves.

Women with androgenic alopecia may be effectively treated with topical minoxidil 2% solution applied twice daily to a dry scalp. Hypertrichosis is an unwanted side effect of topical minoxidil, occurring in 3–5% of treated women; it may affect the forehead, cheeks, upper lip, or chin. Hypertrichosis resolves within 1–6 months after the drug is stopped.

Note: Antiandrogen treatments must be given only to nonpregnant women. Women must be counseled to take oral contraceptives, when indicated, and avoid pregnancy, since use during pregnancy causes malformations and pseudohermaphroditism in male infants.

Primary Aldosteronism

Essentials of Diagnosis

- Hypertension that may be severe or drug-resistant.
- Hypokalemia (in minority of patients) may cause polyuria, polydipsia, muscle weakness.
- Elevated plasma and urine aldosterone levels and low plasma renin level.

General Considerations

Primary aldosteronism (hyperaldosteronism) is common, accounting for 5–10% of all cases of hypertension. Patients of all ages may be affected, but the peak incidence is between 30–60 years. Excessive aldosterone production increases sodium retention and suppresses plasma renin. It increases renal potassium excretion that can lead to hypokalemia. Cardiovascular events are more prevalent in patients with aldosteronism (35%) than in those with essential hypertension (11%). Primary aldosteronism is most commonly caused by an adrenal adenoma (Conn syndrome), and unilateral or bilateral adrenal hyperplasia. Bilateral aldosteronism may be corticosteroid suppressible, due to an autosomal-dominant genetic defect allowing ACTH stimulation of aldosterone production.

Clinical Findings

Symptoms and Signs

Patients have hypertension that is typically moderate. Some patients have only diastolic hypertension, without other symptoms and signs. Malignant hypertension is rare. Edema is rarely seen in primary aldosteronism. About 37% of patients have hypokalemia and may consequently have symptoms of muscular weakness (at times with paralysis simulating periodic paralysis), paresthesias with frank tetany, headache, polyuria, and polydipsia.

Laboratory Findings

Ideally, all hypertensive patients should be screened for hyperaldosteronism prior to treatment. Such screening can include PRA. About 20% of hypertensive patients have a low PRA, and a significant portion of these patients have primary aldosteronism. Initial screening can also include both PRA and aldosterone to determine a renin:aldosterone ratio (see below).

Plasma potassium should also be determined in all hypertensive individuals. However, hypokalemia, once thought to be the hallmark of hyperaldosteronism, is present in only 37% of affected patients: 50% of those with an adrenal adenoma and 17% of those with adrenal hyperplasia. Proper phlebotomy technique is important to avoid spurious increases in potassium. The blood should be drawn slowly with a syringe and needle (rather than a vacutainer) at least 5 seconds after tourniquet release and without fist-clenching. Plasma potassium should be measured, with the separation of plasma from cells within 30 minutes of collection. Besides hypokalemia, many patients with primary aldosteronism also have metabolic alkalosis with an elevated serum bicarbonate (HCO^{-}_{3}) concentration.

Testing for primary aldosteronism should be done for all hypertensive patients with hypokalemia, whether spontaneous or diuretic induced. But since only a minority of patients have hypokalemia, testing should also be considered for normokalemic hypertensive patients with (1) treatment-resistant hypertension (despite three drugs); (2) severe hypertension: > 160 mm Hg systolic or > 100 mm Hg diastolic; (3) early-onset hypertension; (4) low-renin hypertension; (5) hypertension with an adrenal mass; and (6) family history of aldosteronism.

For a patient to be properly tested for primary aldosteronism, certain antihypertensive medications should ideally be held. Diuretics should be discontinued for 3 weeks. Dihydropyridine calcium channel blockers can normalize aldosterone secretion, thus interfering with the diagnosis. -Blockers suppress PRA in patients with essential hypertension. ACE inhibitors and -blockers are less likely to affect testing. Antihypertensive medications that have minimal effects on the plasma aldosterone:renin ratio include verapamil, hydralazine, prazosin, doxazosin, and terazosin. However, it may be impractical to hold or change antihypertensive medicines; in such cases, testing should proceed.

During the testing period, the patient should have an unrestricted high sodium intake. The patient should be out of bed for at least 2 hours and seated for 5–15 minutes before the blood draw, which should preferably be obtained between 8 am and 10 am. Renin is measured as either PRA or direct renin concentration. Serum aldosterone should ideally be measured with a tandem mass spectrometry assay.

For patients who have not been receiving diuretics for at least 3 weeks, a plasma renin that is normal or elevated makes primary aldosteronism very unlikely. However, a low plasma renin is insufficient to establish the presence of primary aldosteronism, since many patients with essential hypertension have low plasma renin activity. A plasma aldosterone:renin ratio is a sensitive screening test. Plasma aldosterone (ng/dL):PRA (ng/mL/h) ratios < 24 exclude primary aldosteronism, whereas ratios between 24 and 67 are suspicious and ratios > 67 are very suggestive of primary aldosteronism. Such elevated ratios are not diagnostic; rather, they indicate the need to document increased aldosterone secretion with a 24-hour urine collection. Another problem with the aldosterone:renin ratio is the use of different units and measurements. For aldosterone, 1 ng/dL converts to 27.7 pmol/L. For renin, a PRA of 1 ng/mL/h (12.8 pmol/L/min) converts to a direct renin concentration of 5.2 ng/L (8.2 mU/L).

When the aldosterone:renin ratio is high, a 24-hour urine collection is assayed for aldosterone, free cortisol, and creatinine. A low PRA (< 5 mcg/L/h) with a urine aldosterone over 20 mcg/24 h indicates primary aldosteronism.

Once primary aldosteronism is diagnosed, unilateral adrenal aldosteronism may be distinguished from bilateral adrenal aldosteronism by adrenal vein sampling (see below) and by further biochemical testing. Plasma may be assayed for 18-hydroxycorticosterone; a level > 100 ng/dL is seen with adrenal neoplasms, whereas levels < 100 ng/dL are nondiagnostic. In addition, a posture stimulation test may be performed, but this requires overnight hospitalization. The test is performed by drawing blood for aldosterone at 8 am while the patient is supine after overnight recumbency and again after the patient is upright for 4 hours. Patients with a unilateral adrenal adenoma usually have a baseline plasma aldosterone level > 20 ng/dL that does not rise. Patients with bilateral adrenal hyperplasia typically have a baseline plasma aldosterone level < 20 ng/dL that rises during upright posture. The accuracy of the posture stimulation test is about 85%.

Imaging

All patients with biochemically confirmed primary aldosteronism require a thin-section CT scan of the adrenals to screen for a rare adrenal carcinoma. In the absence of a large adrenal carcinoma, adrenal CT scanning cannot reliably distinguish unilateral from bilateral aldosterone excess, having a sensitivity of 78% and a specificity of 78% for unilateral aldosteronism.

Therefore, the decision to perform a unilateral adrenalectomy should not be based solely on an adrenal CT scan. Instead, patients with primary aldosteronism should be considered for a trial of medical therapy with spironolactone or eplerenone (see below). If medical therapy is ineffective or if surgery is desired for an apparent adrenal adenoma, further evaluation for surgical candidacy should be done with laboratory testing (see above). However, since CT scanning and laboratory testing is often inconclusive, adrenal vein sampling is often required.

Adrenal Vein Sampling

Bilateral selective adrenal vein sampling is the most accurate way to determine whether primary aldosteronism is due to unilateral aldosterone excess, which can be treated by adrenalectomy. It is indicated only to direct the surgeon to the correct adrenal and should be performed only if surgery is contemplated. It is particularly useful for patients who are not hypokalemic, who are over age 40 years, or who have an adrenal adenoma < 1 cm diameter. It is particularly difficult to catheterize the right adrenal vein. Therefore, the venous samples are assayed for both aldosterone and cortisol during a cosyntropin ($ACTH_{1–24}$) infusion to be sure that the sampling has included both adrenal veins. The procedure has a sensitivity of 95% and a specificity of 100% but only when performed by an experienced radiologist. The complication rate is 2.5%. Risks can be minimized if the radiologist avoids adrenal venography and limits the use of contrast.

Differential Diagnosis

The differential diagnosis of primary aldosteronism includes other causes of hypokalemia (see Chapter 21: Fluid & Electrolyte Disorders) in patients with essential hypertension, especially diuretic therapy. Chronic depletion of intravascular volume stimulates renin secretion and secondary hyperaldosteronism. Thus, it is important to discontinue diuretics and ensure adequate hydration and sodium intake when assessing a patient for primary hyperaldosteronism (see above).

Excessive ingestion of real licorice (black and derived from anise) can cause hypertension and hypokalemia. Licorice contains glycrrhizinic acid, which has a metabolite that inhibits the adrenal enzyme 11 -hydroxysteroid dehydrogenase, thereby blocking the production of cortisol and causing accumulation of the precursor mineralocorticoid deoxycorticosterone. Oral contraceptives may increase aldosterone secretion in some patients. Renal vascular disease can cause severe hypertension with hypokalemia; PRA is high, distinguishing it from primary aldosteronism.

Excessive adrenal secretion of other corticosteroids (besides aldosterone) may also cause hypertension with hypokalemia. This occurs with certain congenital adrenal enzyme disorders such as P450c11 deficiency (increased deoxycorticosterone with virilization and deficient cortisol) or P450c17 deficiency (increased deoxycorticosterone, corticosterone, and progesterone but deficient estradiol and testosterone). P450c17 deficiency results from a defect in the 17-hydroxylase enzyme in both the adrenal and ovarian steroidogenic pathways. Presenting signs include hypertension and ambiguous genitalia or primary amenorrhea. Urinary aldosterone secretion is less than 20 mcg/24 h and plasma renin is low in both P450c11 and P450c17 deficiencies. Primary cortisol resistance can cause hypertension and hypokalemia; renin and aldosterone are suppressed, while plasma levels of cortisol, ACTH, and deoxycorticosterone are high. Liddle syndrome is an autosomal dominant cause of hypertension and hypokalemia resulting from excessive sodium absorption from the renal tubule; renin and aldosterone levels are low. Thyrotoxicosis and familial periodic paralysis may also present with hypokalemia. Hyperaldosteronism may rarely be due to a malignant ovarian tumor.

Complications

The incidence of cardiovascular complications from hypertension are higher in primary aldosteronism than in idiopathic hypertension. Following unilateral adrenalectomy for Conn syndrome, suppression of the contralateral adrenal may result in temporary postoperative hypoaldosteronism, characterized by hyperkalemia and hypotension.

Treatment

Conn syndrome (unilateral aldosterone-secreting adrenal adenoma) is treated by laparoscopic adrenalectomy, though long-term therapy with spironolactone or eplerenone is an option. Bilateral adrenal hyperplasia is best treated with spironolactone or eplerenone. Spironolactone also has anti-androgen activity and frequently causes breast tenderness, gynecomastia, or reduced libido; it is given at initial doses of 12.5–25 mg once daily. Eplerenone is becoming favored for men since it does not have anti-androgen effects; it is usually given at an initial dose of 25 mg twice daily. Eplerenone is metabolized by hepatic CYP 3A4 and drugs that inhibit or compete for this enzyme may increase serum eplerenone levels excessively. Blood pressure must be monitored daily when beginning these anti-mineralocorticoid medications; significant drops in blood pressure have occurred when these drugs are added to other antihypertensives. Other antihypertensive drugs may also be required. Glucocorticoid-remediable aldosteronism is very rare but may respond well to suppression with low-dose dexamethasone.

Prognosis

The hypertension is reversible in about two-thirds of cases but persists or returns in spite of surgery in the remainder. The prognosis is much improved by early diagnosis and treatment. Only 2% of aldosterone-secreting adrenal tumors are malignant.

Pheochromocytoma & Paraganglioma

Essentials of Diagnosis

- "Attacks" of headache, perspiration, palpitations, anxiety.
- Hypertension, frequently sustained but often paroxysmal, especially during surgery or delivery.
- Elevated urinary catecholamines or their metabolites. Normal serum T_4 and TSH.

General Considerations

Both pheochromocytomas and non–head-neck paragangliomas are tumors of the sympathetic nervous system. Pheochromocytomas arise from the adrenal medulla and usually secrete both epinephrine and norepinephrine. Paragangliomas ("extra-adrenal pheochromocytomas") arise from sympathetic paraganglia, often metastasize, and secrete norepinephrine or are nonsecretory. Excessive levels of norepinephrine or neuropeptide Y cause hypertension, while epinephrine causes tachyarrhythmias. These tumors may be located in either or both adrenals or anywhere along the sympathetic nervous chain, and rarely in such aberrant locations as the mediastinum, heart, or bladder.

These rare tumors are deceptive and deadly. They are a rare cause of hypertension, being found in less than 0.3% of hypertensive individuals. The incidence is higher in patients with moderate to severe hypertension. About two to three new cases per million population are diagnosed annually. However, in autopsy cases, the incidence of pheochromocytoma is 250–1300 cases per million, indicating that most cases are not diagnosed during life.

About 25% of patients with pheochromocytomas/paragangliomas harbor germline mutations making them prone to develop the tumor. The chance of harboring a germline mutation is nearly 100%

in patients with a family history of pheochromocytomas/paragangliomas and 17% in patients without any known family history of pheochromocytomas/paragangliomas.

Pheochromocytomas develop in about 20% of patients with type 2 von Hippel–Lindau (VHL) disease (hemangiomas of the retina, cerebellum, brainstem, and spinal cord; hyperparathyroidism; pancreatic cysts; endolymphatic sac tumors; cystadenomas of the adnexa or epididymis; renal cysts, adenomas, and carcinomas); inheritance is autosomal dominant. Patients with VHL develop pheochromocytomas that are less likely to be malignant or extra-adrenal, more likely to be bilateral, and more likely to present at an early age. Pheochromocytomas that arise in patients with VHL secrete exclusively norepinephrine and its metabolite normetanephrine. Therefore, individuals who carry type 2 VHL mutations should be screened for pheochromocytoma with plasma normetanephrine levels.

MEN 2A is associated with pheochromocytomas and medullary thyroid carcinoma. *MEN 2B* is associated with pheochromocytomas, aggressive medullary thyroid carcinoma, mucosal neuromas, and marfinoid habitus. *von Recklinghausen neurofibromatosis type 1 (NF-1)* is associated with an increased risk of pheochromocytomas/paragangliomas as well as cutaneous neurofibromas, optic gliomas, vascular anomalies, hamartomas, malignant nerve sheath tumors, and smooth-bordered café au lait spots. *Familial paraganglioma* can be caused by mutations in the genes encoding suscinate dehydrogenase (SDH) subunits B, C, or D. Patients with such germline mutations are more apt to have bilateral pheochromocytomas or multicentric paragangliomas.

Clinical Findings

Symptoms and Signs

Pheochromocytomas can be lethal unless they are diagnosed and treated appropriately. They typically cause attacks or "paroxysms" that can be spontaneous or triggered by exercise, bending, lifting, emotional stress, surgery, or minor procedures. Certain drugs can precipitate attacks: monoamine oxidase (MAO) inhibitors, caffeine, nicotine, decongestants, amphetamines, cocaine, ionic intravenous contrast, and epinephrine. Bladder paragangliomas may present with paroxysms during micturation. Paroxysms typically produce hypertension and symptoms such as severe headache (80%), perspiration (70%), and palpitations (60%); other symptoms may include anxiety (50%), a sense of impending doom, or tremor (40%). Vasomotor changes during an attack cause mottled cyanosis and facial pallor; as the attack subsides, facial flushing may occur as a result of reflex vasodilation. Epinephrine secretion by an adrenal pheochromocytoma may cause episodic tachyarrhythmias, hypotension, or even syncope. Acute coronary syndrome can be caused by coronary vasoconstriction. Confusion, psychosis, seizures, transient ischemic attacks, or stroke may occur with cerebrovascular vasoconstriction or hemorrhagic stroke. Aortic aneurysms may dissect and rupture. Abdominal pain, nausea, vomiting, and even ischemic bowel can be due to splanchnic vasoconstriction. Large or hemorrhagic abdominal tumors can also cause abdominal pain. Peripheral vasoconstriction can cause Raynaud phenomenon or even gangrene. Patients may experience nervousness and irritability, increased appetite, and loss of weight. Other patients have pulmonary edema and heart failure due to cardiomyopathy. Cytokine release can cause nephrotic syndrome or acute respiratory distress syndrome (ARDS). Other manifestations can include hyperglycemia, bradycardia, constipation, and paresthesias.

Physical findings usually include hypertension (90% of patients), which may be sustained (20% of patients), sustained with paroxysms (50% of patients), or paroxysmal only (25% of patients). Postural changes in blood pressure and pulse are often encountered, with blood pressure decreasing and pulse increasing (change of > 20 beats/min) after arising from a supine to a standing position. There may be cardiac enlargement and cardiomyopathy. Fever and elevation of basal body temperature can occur. Retinal hemorrhage or cerebrovascular hemorrhage occurs occasionally. Although most patients are symptomatic, some patients are normotensive and asymptomatic, particularly when the tumor is nonsecretory or discovered at an early stage.

Catastrophic hypertensive crisis and fatal cardiac arrhythmias can occur spontaneously or may be triggered by intravenous contrast dye or glucagon injection, needle biopsy of the mass, anesthesia, and surgical procedures.

In addition to catecholamines and their metabolites, pheochromocytomas secrete a wide range of other peptides that can sometimes cause symptoms of Cushing syndrome (ACTH), erythrocytosis (erythropoietin), or hypercalcemia (PTHrP).

Laboratory Findings

Plasma fractionated free metanephrines is the single most sensitive test for secretory pheochromocytomas and paragangliomas. Normal levels rule out pheochromocytoma and paraganglioma with some certainty and the work-up can usually end there. However, misleading elevations in metanephrines or normetanephrines can be caused by factors such as physical or emotional stress, sleep apnea, and MAO inhibitors. Therefore, patients with elevated plasma metanephrines or normetanephrines levels require further evaluation.

Assay of urinary fractionated metanephrines and creatinine effectively confirms most pheochromocytomas that were detected by elevated plasma fractionated metanephrines. A 24-hour urine specimen is usually obtained, although an overnight or shorter collection may be used; patients with pheochromocytomas generally have more that 2.2 mcg of total metanephrine per milligram of creatinine, and more than 135 mcg total catecholamines per gram creatinine. Urinary assay for total metanephrines is about 97% sensitive for detecting functioning pheochromocytomas. Urinary assay for vanillylmandelic acid (VMA) is about 89% sensitive and is not usually required.

Some drugs and foods can interfere with certain assays for catecholamines, and stresses can also cause misleading elevations in catecholamine excretion (Table 26–12). About 10% of hypertensive patients have a misleadingly elevated level of one or more tests.

Table 26–12. Factors potentially causing misleading catecholamine results: High-performance liquid chromatography with electrochemical detection (HPLC-ECD).

Drugs	**Foods**	**Conditions**
Acetaminophen[2]	Bananas[1]	Amyotrophic lateral sclerosis[1]
Aldomet[2]	Caffeine[1]	Brain lesions[1]
Amphetamines[1]	Coffee[2]	Carcinoid[1]
Bronchodilators[1]	Peppers[2]	Eclampsia[1]
Buspirone[2]		Emotion, severe[1]

Phenoxybenzamine		
Tricyclic anti-depressants		
Viloxazine[2]		

[1] Increases catecholamine excretion.

[2] May cause confounding peaks on HPLC chromatograms.

[3] Decreases catecholamine excretion.

Direct assay of epinephrine and norepinephrine in blood and urine during or following an attack is a sensitive test for pheochromocytoma associated with paroxysmal hypertension. Plasma free metanephrine concentrations may also be used. Proper, quiet collection of plasma specimens is essential.

Serum chromogranin A is elevated in 90% of patients with pheochromocytoma and the levels correlate with tumor size, being higher in patients with metastatic disease. Serum chromogranin A levels can be misleadingly elevated in patients with azotemia or hypergastrinemia, and in those treated with corticosteroids or proton pump inhibitors. Serum may also be assayed for neuron-specific enolase; high levels implicate a malignant pheochromocytoma, while normal levels are nonspecific.

Pharmacologic provocative and suppressive tests that evaluate the rise or fall in blood pressure are usually not required or recommended.

Hyperglycemia is present in about 35% of patients but is usually mild. Leukocytosis is common. The ESR is sometimes elevated. PRA may be increased by catecholamines.

Genetic testing should ideally be performed on all patients with pheochromocytoma or paraganglioma. Testing for VHL, *ret* protooncogene, and SDHB/SDHD mutations is advisable. Family members may then be screened for the specific gene mutation.

Imaging

CT and MRI scanning

Imaging should not usually replace biochemical testing, since incidental adrenal adenomas are common (2–4% of scans) and can be misleading. When a pheochromocytoma is suspected because of biochemical testing or a genetic condition predisposing to pheochromocytoma, a CT scan of the abdomen is performed, with thin sections through the adrenals (see CT scan). *A noncontrast CT should be followed by a CT scan using nonionic contrast, which reduces the risk of catecholamine release from a pheochromocytoma and a hypertensive crisis.* Glucagon should not be used during scanning, since it can provoke hypertensive crisis; similarly, intravenous contrast can precipitate hypertensive crisis, particularly in patients whose hypertension is uncontrolled.

Fig.

Left infrarenal pheochromocytoma shown by CT scanning. The lower diagram identifies many of the visible structures. (Reproduced, with permission, from Greenspan FS, Strewler GJ [editors]: *Basic & Clinical Endocrinology*, 5th ed. Originally published by Appleton & Lange. Copyright © 1997 by The McGraw-Hill Companies, Inc.)

MRI scanning has the advantage of not requiring intravenous contrast dye; its lack of radiation makes it the imaging of choice during pregnancy and childhood. Both CT and MRI scanning have a sensitivity of about 90% for adrenal pheochromocytoma and a sensitivity of 95% for adrenal tumors over 0.5 cm in diameter. However, both CT and MRI are less sensitive for detecting recurrent tumors, metastases, and extra-adrenal paragangliomas. If no adrenal tumor is found, the scan is extended to include the entire abdomen, pelvis, and chest.

Nuclear imaging

A whole-body [^{123}I]*m*-Iodobenzylguanidine (^{123}I-MIBG) scan can localize tumors with a sensitivity of 85% and a specificity of 99%. It is less sensitive for MEN 2A- or MEN 2B-related pheochromocytomas. Preoperative ^{123}I-MIBG scanning is not usually required to confirm that a unilateral adrenal mass is a pheochromocytoma in a patient with classic clinical and biochemical presentation. Preoperative whole-body ^{123}I-MIBG scanning can be useful when the CT scan cannot locate a suspected pheochromocytoma, making a paraganglioma more likely; it can also be useful when the CT scan is ambiguous for pheochromocytoma. It is prudent to perform a whole-body ^{123}I-MIBG scan about 3 months postoperatively to determine if metastatic or recurrent tumor is present. Drugs that reduce ^{123}I-MIBG uptake should be avoided, including tricyclic antidepressants and cyclobenzaprine (6 weeks), amphetamines, nasal decongestants, phenothiazines, haloperidol, diet pills, labetalol, and cocaine (2 weeks).

Somatostatin receptor imaging using ^{111}In-labeled octreotide is only 25% sensitive for detecting an adrenal pheochromocytoma. However, ^{111}In-labeled octreotide scanning is quite sensitive for detecting extra-adrenal pheochromocytomas (paragangliomas) and metastatic pheochromocytomas, sometimes locating tumors that were missed by ^{123}I-MIBG scanning.

PET scanning usually detects tumors using ^{18}F-labeled deoxyglucose (^{18}FDG-PET) or ^{18}F-labeled dopamine (^{18}FDA-PET), and may demonstrate tumors that are not visible on ^{123}I-MIBG scanning. Combining PET scan with noncontrast CT produces a PET/CT fusion scan with exceptional sensitivity.

Differential Diagnosis

Pheochromocytoma may be misdiagnosed as thyrotoxicosis, essential hypertension, myocarditis, glomerulonephritis or other renal lesions, toxemia of pregnancy, eclampsia, and psychoneurosis (anxiety attack). It can sometimes be mistaken for an acute abdomen.

Conditions that have manifestations similar to those of pheochromocytoma include the following: essential labile hypertension, renal hypertension, anxiety attacks, thyrotoxicosis, toxemia of pregnancy, acute intermittent porphyria, hypogonadal vascular instability (hot flushes), cocaine or amphetamine use, and clonidine withdrawal. Patients taking nonselective MAO inhibitor antidepressants can have hypertensive crisis after eating foods that contain tyramine (eg, fermented cheeses, aged wines, certain beers, fava beans, vegemite, marmite). Patients with erythromelalgia can have hypertensive crises; their episodic painful flushing and leg swelling are relieved by cold, distinguishing this condition from pheochromocytoma. Pheochromocytomas can cause chest pain and ECG changes that mimic acute cardiac ischemia. Renal artery stenosis can cause severe hypertension and may coexist with pheochromocytoma.

False-positive testing for catecholamines and metabolites occurs in about 10% of hypertensives, but levels are usually less than 50% above normal and typically normalize with repeat testing.

Complications

All of the complications of severe hypertension may be encountered. In addition, a catecholamine-induced cardiomyopathy may develop. Severe heart failure and cardiovascular collapse may develop in patients during a paroxysm. Sudden death may occur due to cardiac arrhythmia. ARDS has been reported. Hypertensive crises with sudden blindness or cerebrovascular accidents are not uncommon. Paroxysms may be precipitated by sudden movement, by manipulation during or after pregnancy, by emotional stress or trauma, or during surgical removal of the tumor. Decongestant medications, fluoxetine, and other selective serotonin reuptake inhibitors may induce hypertensive paroxysms and death. Occasionally, the initial manifestation of pheochromocytoma may be hypotension or even shock.

After removal of the tumor, a state of severe hypotension and shock (resistant to epinephrine and norepinephrine) may ensue with precipitation of kidney disease or myocardial infarction. Hypotension and shock may occur from spontaneous infarction or hemorrhage of the tumor.

On rare occasions, a patient dies as a result of the complications of diagnostic tests or during surgery.

During surgery, pheochromocytoma cells may be seeded within the peritoneum, resulting in multifocal recurrent tumors.

Medical Treatment

Patients must receive adequate treatment for hypertension and tachyarrhythmias prior to surgery for pheochromocytoma/paraganglioma. Patients are advised to use a portable sphyngomanometer and measure their blood pressures daily and immediately during paroxysms.

-Blockers (prazocin or phenoxybenzamine) are typically administered preparatory to surgery. Many surgeons insist upon -blockade preoperatively. Phenoxybenzamine is given initially in a dosage of 10 mg orally every 12 hours, increasing gradually—about every 3 days—until hypertension is controlled. Maintenance doses range from 10 mg/d to 120 mg/d. Optimal -blockade is achieved when supine arterial pressure is below 140/90 mm Hg or as low as possible for the patient to have a standing arterial pressure above 80/45 mm Hg.

Calcium channel blockers (nifedipine ER or nicardipine ER) are very effective and may be used with or without -blockers. They are superior to phenoxybenzamine for long-term use, since they cause less fatigue, nasal congestion, and orthostatic hypotension. For acute hypertensive crisis (systolic blood pressure > 170 mm Hg) a nifedipine 10-mg capsule may be chewed and swallowed. Nifedipine is quite successful for treating acute hypertension in patients with pheochromocytoma/paraganglioma, even at home; it is reasonably safe as long as the blood pressure is monitored.

-Blockers (eg, metoprolol XL) are required by most patients after institution of -blockade or calcium channel blockade. The use of a -blocker as initial antihypertensive therapy has resulted in "unopposed alpha" that causes paradoxical worsening of hypertension. Labetalol has combined - and -blocking activity and is an effective agent but can cause paradoxical hypertension if used as the initial antihypertensive agent. Labetalol can also interfere with catecholamine determinations in some laboratories and reduces the tumor's uptake-1, such that it must be discontinued for at least 4–7 days before diagnostic scanning with ^{123}I-MIBG or ^{18}FDA-PET or ^{131}I-MIBG therapy.

Surgical Treatment

Surgical removal of pheochromocytomas or abdominal paragangliomas is the treatment of choice. For surgery, a team approach—endocrinologist, anesthesiologist, and surgeon—is critically important. Laparoscopic surgery is preferred, but large and invasive tumors require open laparotomy. Patients with small familial or bilateral pheochromocytomas may undergo selective resection of the tumors, sparing the adrenal cortex; however, there is a recurrence rate of 10% over 10 years.

Prior to surgery, blood pressure control should be maintained for a minimum of 4–7 days or until optimal cardiac status is established. The ECG should be monitored until it becomes stable. (It may take a week or even months to correct ECG changes in patients with catecholamine myocarditis, and it may be prudent to defer surgery until then in such cases.) Patients must be very closely monitored during surgery to promptly detect sudden changes in blood pressure or cardiac arrhythmias.

Intraoperative severe hypertension is managed with continuous intravenous nicardipine (a short-acting calcium channel blocker), 2–6 mcg/kg/min, or nitroprusside, 0.5–10 mcg/kg/min. Prolonged nitroprusside administration can cause cyanide toxicity. Tachyarrhythmia is treated with intravenous atenolol (1 mg boluses), esmolol, or lidocaine.

Autotransfusion of 1–2 units of blood at 12 hours preoperatively plus generous intraoperative volume replacement reduces the risk of postresection hypotension caused by desensitization of the vascular $_1$-receptors. Shock may therefore occur following removal of the pheochromocytoma. It is treated with intravenous saline or colloid and high doses of intravenous norepinephrine. Intravenous 5% dextrose is infused postoperatively to prevent hypoglycemia.

Surgical histopathology for pheochromocytoma/paraganglioma cannot reliably determine whether a tumor is malignant. Therefore, all pheochromocytomas and paragangliomas must be approached as possibly malignant. Even if no metastases are visible at the time of surgery, patients require lifetime follow-up. Therefore, it is essential to recheck plasma fractionated metanephrine levels postoperatively, at least 2–4 weeks after surgery and when the patient has minimal residual pain. It is also prudent to perform a whole-body [^{123}I]mIBG scan about 3 months postoperatively, since previously undetected metastases may become visible. Thereafter, blood pressure and symptoms must be rechecked regularly for life; plasma fractionated metanephrines are also rechecked regularly, at least every 6 months for 5 years, and immediately if hypertension or symptoms recur or if metastases become evident.

For inoperable or metastatic tumors, metyrosine reduces catecholamine synthesis; the initial dosage is 250 mg four times daily, increased daily by increments of 250–500 mg to a maximum of 4 g/d. Metyrosine causes central nervous system side effects and crystalluria; hydration must be ensured. Metastatic pheochromocytomas may be treated with combination chemotherapy (eg, cyclophosphamide, vincristine, and dacarbazine) or with high doses of ^{131}I-MIBG.

Prognosis

The malignancy of a pheochromocytoma cannot be determined by histologic examination. A tumor is considered malignant if metastases are present; this may take many years to become clinically evident. Therefore, lifetime surveillance is required. Malignancy is more likely for paragangliomas and for large pheochromocytomas (> 7 cm in diameter). The prognosis is good for patients with smaller, benign pheochromocytomas that are resected before causing cardiovascular damage. Hypertension usually resolves after successful surgery but may persist or return in 25% of patients despite successful surgery. Although this may be essential hypertension, biochemical reevaluation is then required, looking for a second or metastatic pheochromocytoma.

Before the advent of blocking agents, the surgical mortality rate was as high as 30%, but this has rapidly decreased. With optimal management, the surgical mortality rate is less than 3%.

Patients with metastatic pheochromocytoma and paraganglioma have a 5-year survival rate of 44% after surgery; patients who have their primary tumor resected and subsequently receive high-dose [^{131}I]mIBG therapy have been reported to have a 5-year survival rate of 75%. Patients with a heavy and increasing tumor burden and distant metastases have a worse prognosis; patients with multiple pulmonary metastases have limited survival. Those with metastases limited to the abdomen have a better prognosis. Some patients have an indolent malignancy and experience a prolonged survival.

Islet Cell Tumors

Essentials of Diagnosis

- Half the tumors are nonsecretory; weight loss, abdominal pain, or jaundice may be presenting signs.
- Secretory tumors cause a variety of manifestations depending upon the hormones secreted.

General Considerations

(Diabetes mellitus and hyperglycemia are discussed in Chapter 27: Diabetes Mellitus & Hypoglycemia.)

The pancreatic islets are composed of several types of cells, each with distinct chemical and microscopic features: the A cells (20%) secrete glucagon, the B cells (70%) secrete insulin, and the D cells (5%) secrete somatostatin or gastrin. F cells secrete "pancreatic polypeptide." Although most pancreatic and duodenal neuroendocrine tumors arise spontaneously, they may occur as part four different inherited disorders: multiple endocrine neoplasia type 1 (MEN 1), von Hippel-Lindau disease (VHL), neurofibromatosis 1 (NF-1) and the rare tuberous sclerosis complex (TSC).

Insulinomas are usually (about 82%) benign and secrete excessive amounts of insulin (as well as proinsulin and C-peptide), which causes hypoglycemia. The tumors may be multiple, especially in familial MEN 1—about 12% of cases (see Chapter 27: Diabetes Mellitus & Hypoglycemia).

Gastrinomas secrete excessive quantities of the hormone gastrin (as well as "big" gastrin), which stimulates the stomach to hypersecrete acid, thereby causing hyperplastic gastric rugae and peptic ulceration (Zollinger–Ellison syndrome). Most gastrinomas are benign, but some are malignant and metastasize to the liver. Gastrinomas are typically found in the duodenum (49%), pancreas (24%), or lymph nodes (11%). Sporadic Zollinger–Ellison syndrome is rarely suspected at the onset of symptoms; typically, there is a 5-year delay in diagnosis. About 22% of patients have MEN 1. MEN 1 usually presents in patients who are younger; hyperparathyroidism may occur from 14 years preceding the Zollinger–Ellison diagnosis to 38 years afterward. (See Multiple Endocrine Neoplasia, below.)

Glucagonomas are usually malignant; liver metastases are ordinarily present by the time of diagnosis. They usually secrete other hormones besides glucagon, often gastrin (see photograph).

Fig.

Necrolytic migratory erythema. (Courtesy of C Grunfeld.)

Somatostatinomas are very rare and are associated with weight loss, diabetes mellitus, malabsorption, and hypochlorhydria.

Other rare tumors secrete excessive amounts of **vasoactive intestinal polypeptide (VIP)**, a substance that causes profuse watery diarrhea (Verner–Morrison syndrome).

Clinical Findings

Symptoms and Signs

Presenting symptoms and signs of **gastrinomas** include abdominal pain (75%), diarrhea (73%), heartburn (44%), bleeding (25%), or weight loss (17%). Endoscopy usually discovers prominent gastric folds (94%).

The 5-, 10-, and 20-year survival rates with MEN 1 are 94%, 75%, and 58%, respectively, while the survival rates for sporadic Zollinger–Ellison syndrome are 62%, 50%, and 31%, respectively. (See Chapter 15: Gastrointestinal Disorders.)

Initial symptoms of **glucagonoma** often include weight loss, diarrhea, nausea, peptic ulcer, or necrolytic migratory erythema. About 35% of patients ultimately develop diabetes. The median survival is 2.8 years after diagnosis.

Islet cell tumors can secrete ectopic hormones in addition to native hormones, often in combinations producing a variety of clinical syndromes. They may secrete ACTH, producing Cushing syndrome. Secretion of serotonin can produce an atypical carcinoid syndrome manifested by pain, diarrhea, and weight loss; skin flushing occurs in only 39% of patients. Pancreatic carcinoid tumors grow slowly but usually metastasize to local and distant sites, particularly to other endocrine organs.

Islet cell tumors may be part of the syndrome of multiple endocrine adenomatosis type I (with pituitary and parathyroid adenomas).

Imaging

Localization of noninsulinoma pancreatic islet cell tumors and their metastases is best done with somatostatin receptor scintigraphy (SRS); SRS detects about 75% of noninsulinomas. CT and MRI are also useful. Insulinomas can usually be located preoperatively by endoscopic ultrasonography. For insulinomas, preoperative localization studies are less successful and have the following sensitivities: ultrasonography 25%, CT 25%, endoscopic ultrasonography 27%, transhepatic portal vein sampling 40%, arteriography 45%, intraoperative palpation 55%, and intraoperative pancreatic ultrasound 75%. Nearly all insulinomas can be successfully located at surgery by intraoperative palpation and ultrasound. An abdominal CT scan is usually obtained, but extensive preoperative localization procedures, especially with invasive methods, are not required. Tumors may be located in the pancreatic head or neck (57%), body (15%), or tail (19%) or in the duodenum (9%).

Treatment

Direct resection of the tumor (or tumors), which often spreads locally, is the primary form of therapy for all types of islet cell neoplasm except Zollinger–Ellison syndrome, where use of high doses of a proton pump inhibitor is the therapy of choice (quadruple the usual doses). Note that serum gastrin levels tend to be high in any patient who is taking a proton pump inhibitor; hypercalcemia also stimulates gastrin release. Insulinomas are resected. However, in MEN 1, insulinomas are rarely cured, so surgery is reserved for dominant masses in such cases. Palliation of functioning malignant disease often requires both antihormonal and anticancer chemotherapy. The use of streptozocin, doxorubicin, and asparaginase, especially for malignant insulinoma, has produced some encouraging results, though these drugs are quite toxic (see Table 39–11). The hypoglycemia of insulinoma may be counteracted by verapamil or diazoxide. Octreotide

LAR is useful in the therapy of islet cell tumors with the exception of insulinoma; monthly subcutaneous injections of 20–30 mg are required. Treatment with octreotide improves the symptoms of **VIP** but does not halt tumor growth. Symptomatic improvement with calcitonin treatment has also been reported.

The prognosis in these neoplasms is variable. The surgical complication rate is about 40%, with patients commonly developing fistulas and infections. Extensive pancreatic resection may cause diabetes mellitus. The overall 5-year survival is higher with functional tumors (77%) than with nonfunctional ones (55%) and higher with benign tumors (91%) than with malignant ones (55%).

Male Hypogonadism

Essentials of Diagnosis

- Diminished libido and erections.
- Decreased growth of body hair.
- Testes may be small or normal in size. Serum testosterone is usually decreased.
- Serum gonadotropins (LH and FSH) are decreased in hypogonadotropic hypogonadism; they are increased in testicular failure (hypergonadotropic hypogonadism).

General Considerations

Male hypogonadism is caused by deficient testosterone secretion by the testes. It may be classified according to whether it is due to (1) insufficient gonadotropin secretion by the pituitary (hypogonadotropic) or (2) pathology in the testes themselves (hypergonadotropic) (Table 26–13).

Table 26–13. Causes of male hypogonadism.

Hypogonadotropic (Low or Normal LH)	**Hypergonadotropic (High LH)**
Alcohol	Antitumor chemotherapy
Chronic illness	Bilateral anorchia

Congenital syndromes	Idiopathic
Constitutional delay	Klinefelter syndrome
Cushing syndrome	Leprosy
Drugs	Lymphoma
Estrogen-secreting tumors (testicular, adrenal)	Male climacteric
GnRH agonist (leuprolide)	Mumps
Hemochromatosis	Myotonic dystrophy
Hypopituitarism	Noonan syndrome
Hypothyroidism	Orchitis
Idiopathic	Radiation therapy
Kallmann syndrome	Sertoli cell-only syndrome
Ketoconazole	Testicular trauma
17-Ketosteroid reductase deficiency	Tuberculosis
Malnourishment	Uremia
Marijuana	
Obesity (BMI > 40)	
Prader–Willi syndrome	
Prior androgens	
Spironolactone	

BMI, body mass index; GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone.

Etiology

Hypogonadotropic Hypogonadism

A deficiency in FSH and LH may be isolated or associated with other pituitary hormonal abnormalities. (See Hypopituitarism.) Patients must be evaluated for signs of Cushing syndrome or adrenal insufficiency, growth hormone excess or deficiency, and thyroid hormone excess or deficiency.

Acquired hypogonadotropic hypogonadism may be due to pituitary or hypothalamic factors but may be idiopathic. Hyperprolactinemia (see Table 26–2) may also induce hypogonadism.

Hypogonadotropic hypogonadism can develop in men receiving GnRH agonist therapy for prostate cancer and can persist following cessation of therapy.

Hypergonadotropic Hypogonadism

A failure in testicular secretion of testosterone causes a rise in LH. If testicular Sertoli cell function is deficient, FSH will be elevated. Conditions that can cause testicular failure include viral infection (eg, mumps), irradiation, cancer chemotherapy, autoimmunity, myotonic dystrophy, uremia, XY gonadal dysgenesis, partial 17-ketosteroid reductase deficiency, Klinefelter syndrome, and male climacteric.

Klinefelter syndrome (47,XXY and its variants) is the most common chromosomal abnormality among males, with an incidence of about 1:500. It is caused by the expression of an abnormal karyotype, classically 47,XXY. Other forms are common, eg, 46,XY/47,XXY mosaicism, 48,XXYY, 48,XXXY, or 46,XX males.

The manifestations of Klinefelter syndrome are variable. Testes feel normal during childhood, but during adolescence they usually become firm, fibrotic, small, and nontender to palpation. Although puberty occurs at the normal time, the degree of virilization is variable. About 85% of patients have some gynecomastia at puberty.

Other common findings include tall stature and abnormal body proportions that are unusual for hypogonadal men (height greater than arm span; crown-pubis length greater than pubis-floor). Patients with multiple X or Y chromosomes are more apt to have mental deficiency and other abnormalities such as clinodactyly or synostosis. They may also exhibit problems with coordination and social skills. Other problems include a higher incidence of breast cancer, chronic pulmonary disease, varicosities of the legs, and diabetes mellitus (8% of patients); impaired glucose tolerance occurs in an additional 19% of patients.

On semen analysis, most men (about 95%) with classic Klinfelter syndrome have azoospermia, but men with 46,XY/47,XXY mosaicism may have spontaneous fertility. Also, testicular biopsy reveals sperm in up to 50% of affected patients, allowing some of them to be fertile with the use of in vitro fertilization using intracytoplasmic sperm injection (ICSI). The diagnosis is confirmed by karyotyping or by determining the presence of RNA for X-inactive-specific transcriptase (XIST) in peripheral blood leukocytes by polymerase chain reaction.

All causes of gynecomastia (see Table 26–14) must be differentiated from Klinefelter syndrome.

Table 26–14. Causes of gynecomastia.

Idiopathic	Bicalutamide
	Busulfan
Physiologic causes	Chorionic gonadotropin
Neonatal period	Cimetidine
Puberty	Clomiphene
Aging	Cyclophosphamide
Obesity	Diazepam
	Diethylstilbestrol
Endocrine diseases	Digitalis preparations

Androgen resistance syndromes	Estrogens (oral or topical)
	Ethionamide
Aromatase excess syndrome (sporadic or familial)	Finasteride
	Flutamide
	Goserelin
Diabetic lymphocytic mastitis	HAART (highly active antiretroviral therapy)
Hyperprolactinemia	Haloperidol
Hyperthyroidism	Hydroxyzine
Klinefelter syndrome	Isoniazid
Male hypogonadism	Ketoconazole
Partial 17-ketosteroid reductase deficiency	Leuprolide
	Marijuana
	Meprobamate
Systemic diseases	Methadone
Chronic liver disease	Methyldopa
Chronic kidney disease	Metoclopramide
Neurologic disorders	Mirtazapine
Refeeding after starvation	Molindone
Spinal cord injury	Nilutamide
	Omeprazole
	Opioids
Neoplasms	Penicillamine

Adrenal tumors	Phenothiazines
Bronchogenic carcinoma	Progestins
Carcinoma of the breast	Protease inhibitors
Hepatocellular carcinoma (rare)	Reserpine
	Risperidone
Testicular tumors	Somatropin (growth hormone)
Drugs (partial list)	Soy ingestion
Alcohol	Spironolactone
Alkylating agents	Testosterone
Amiodarone	Thioridazine
Anabolic steroids	Tricyclic antidepressants
Androgens	
Bicalutamide	

Androgen Insensitivity

Partial resistance to testosterone is a rare condition in which phenotypic males have variable degrees of apparent hypogonadism, hypospadias, cryptorchism, and gynecomastia. Serum testosterone levels are normal.

Clinical Findings

Symptoms and Signs

Hypogonadism that is congenital or acquired during childhood presents as delayed puberty. Men with acquired hypogonadism have variable manifestations. Most men experience decreased libido. Others complain of erectile dysfunction, hot sweats, fatigue, or depression. Their presenting complaint may also be infertility, gynecomastia, headache, fracture, or other symptoms related to the cause or result of the hypogonadism. The patient's history often gives a clue to the cause (Table 26–13).

Physical signs associated with hypogonadism may include decreased body, axillary, beard, or pubic hair; such diminished sexual hair growth is not reliably present except after years of severe hypogonadism (see photograph). Men in whom hypogonadism develops tend to lose muscle mass and gain weight due to an increase in subcutaneous fat. Examination should include measurements of arm span and height. Testicular size should be assessed with an orchidometer (normal volume is about 10–25 mL; normal length is usually over 6 cm). Testicular size may decrease but usually remains within the normal range in men with postpubertal hypogonadotropic hypogonadism, but it may be diminished with testicular injury or Klinefelter syndrome. The testes must also be carefully palpated for masses, since Leydig cell tumors may secrete estrogen and present with hypogonadism. The testicles must be carefully examined for evidence of trauma, infiltrative lesions (eg, lymphoma), or ongoing infection (eg, leprosy, tuberculosis).

Fig.

Boy, 15 years old with Kallmann's syndrome. His testes were originally undescended, but they descended into the scrotum after human chorionic gonadotropin treatment was given. His height was 163.9 cm (–1.5 SD), and the US:LS ratio was 0.86 (eunuchoid). The penis was 6.3 x 1.8 cm. Each testis was 1 x 2 cm. Plasma luteinizing hormone was not detectable and rose to 5.5 mIU/mL (0.7 ng/mL) after administration of 100 mg of gonadotropin-releasing hormone; follicle-stimulating hormone rose from 3.6 to 7.2 mU/mL (1.2–2.4 ng/mL). Testosterone did not change from 17 ng/dL. He had no ability to smell standard odors. (Reproduced, with permission, from Styne DM, Grumbach MM: *Reproductive Endocrinology*. Yen SSC, Jaffe RB [editors]. Saunders, 1978.)

Laboratory Findings

The evaluation for hypogonadism begins with a morning serum testosterone or free testosterone measurement.

Normal ranges for serum testosterone have been derived from nonfasting morning blood specimens, which tend to be the highest of the day. Later in the day, serum testosterone levels can be 25–50% lower. Therefore, a serum testosterone drawn fasting or late in the day may be misleadingly below the "normal range." Serum testosterone levels in men are highest at age 20–30 years and slightly lower at age 30–40 years; testosterone falls gradually but progressively after age 40 years. Testing for serum free testosterone is especially important for detecting hypogonadism in elderly men, who generally have high levels of SHBG. A low serum testosterone is evaluated with serum LH and FSH levels. LH and FSH tend to be high in patients with hypergonadotropic hypogonadism but low or inappropriately normal in men with hypogonadotropic hypogonadism. Patients with low gonadotropins are further evaluated for other pituitary abnormalities, including hyperprolactinemia.

Testosterone stimulates erythropoiesis in men, causing the normal red blood count range to be higher in men than in women; mild anemia is common in men with hypogonadism, with red blood counts below the normal male range. For men with long-standing male hypogonadism, bone densitometry is recommended. Men with severe osteoporosis may require treatment with bisphosphonates and vitamin D, in addition to testosterone replacement therapy. (See Osteoporosis section.)

Most radioimmunoassays and ELISA for testosterone are inaccurate below serum testosterone levels of 300 ng/dL. The more accurate testosterone assays rely upon extraction and chromatography, followed by mass spectrometry or immunoassay. Free testosterone is best measured by calculation, using accurate assays for testosterone and SHBG.

Hypogonadotropic hypogonadism

A serum PRL determination is obtained but may be elevated for many reasons (see Table 26–2). Men with gynecomastia may be screened for partial 17-ketosteroid reductase deficiency with serum determinations for androstenedione and estrone, which are elevated in this condition. X-linked congenital adrenal hypoplasia is a rare condition in which a *DAX-1* gene mutation causes hypogonadotropic hypogonadism and azoospermia, which usually presents in adolescence; the associated primary adrenal insufficiency usually presents in childhood, but it may remain undiagnosed into adulthood. The serum estradiol level may be elevated in patients with cirrhosis and in rare cases of estrogen-secreting tumors (testicular Leydig cell tumor or adrenal carcinoma). Men with no discernible definite cause for hypogonadotropic hypogonadism should be screened for hemochromatosis and have an MRI of the pituitary and hypothalamic region to look for a tumor or other lesion. (See Hypopituitarism.)

Hypergonadotropic hypogonadism

Men with hypergonadotropic hypogonadism have low serum testosterone levels with a compensatory increase in FSH and LH. Klinefelter syndrome can be confirmed by karyotyping or by measurement of leukocyte XIST (see photograph). Testicular biopsy is usually reserved for younger patients in whom the reason for primary hypogonadism is unclear.

Fig.

Klinefelter's syndrome in a 20-year-old man. Note relatively increased lower/upper body segment ratio, gynecomastia, small penis, and sparse body hair with a female pubic hair pattern. (Reproduced, with permission, from Greenspan FS, Strewler GJ [editors]: *Basic & Clinical Endocrinology*, 5th ed. Originally published by Appleton & Lange. Treatment

Testosterone replacement is the usual treatment for hypogonadism. It is prudent to screen older men for prostate cancer before testosterone therapy is begun. Testosterone helps reverse sexual dysfunction and muscle atrophy. Men with Klinefelter syndrome have a reduced risk of developing verbal fluency problems if testosterone therapy is begun at the time of normal puberty.

Topical testosterone gel is the preferred method for administering testosterone. Topical 1% testosterone gel is commercially available as Androgel or Testim (2.5-g and 5-g packets); Androgel is odorless, while Testim has a musky odor. The starting dose is 5 g (50 mg testosterone) applied once daily to clean, dry skin of the shoulders, upper arms, or abdomen. The skin serves as a reservoir that slowly releases about 10% of the testosterone into the blood; serum testosterone levels reach a steady state in 1–3 days. The gel should not be applied to the genitals. The entire contents of a packet are squeezed onto the palm and then immediately applied. After the application of testosterone gel, the hands should be washed. The application site should be allowed to dry for 5–10 minutes before donning a shirt to prevent the gel from rubbing off the skin. A shirt must be worn during contact with women or children to prevent transfer of testosterone to them. The serum testosterone level should be determined about 14 days after starting therapy; if the level remains below normal or the clinical response is inadequate, the daily dose may be increased to 7.5 g or 10 g.

Testosterone transdermal systems (skin patches) are available in two formulations for application to nongenital skin. Testoderm II, 5 mg/d leaves a sticky residue but causes little skin irritation. Androderm adheres more tightly to the skin but may cause more skin irritation. Both produce reliable serum levels of testosterone that are somewhat lower that those achieved with injections. The patch systems also suffer from being rather inconvenient and expensive.

Hypogonadism may also be treated with parenteral testosterone (enanthate or cypionate). The usual dose is about 300 mg intramuscularly in the gluteal area every 3 weeks or 200 mg every 2 weeks. The preparation is oil based and is usually given in the gluteal area. The dose is adjusted according to the patient's response.

Oral androgen preparations include methyltestosterone and fluoxymesterone. These oral preparations have rarely caused liver tumors or peliosis hepatis with long-term use. Cholestatic jaundice occurs in 1–2% of patients but usually remits after the medication is discontinued. The oral androgens are not as effective as parenteral testosterone.

Men with mosaic Klinefelter syndrome (eg, 46,XY/47,XXY) may be fertile. However, men with nonmosaic Klinefelter syndrome (eg, 47,XXY) are usually azoospermic; fertility may be achieved by testicular sperm retrieval and in vitro intracytoplasmic sperm injection (ICSI) into an ovum.

Testosterone replacement therapy may cause a minimal reduction in serum HDL levels and has no effect on LDL levels; testosterone therapy has never been demonstrated to increase the incidence of cardiovascular disease, myocardial infarction, or stroke.

Testosterone therapy can aggravate benign prostatic hypertrophy (BPH). However, aggravation of voiding problems is uncommon. In men with BPH, finasteride may be coadministered with testosterone to reduce prostate size. The incidence of prostate cancer does not appear to be increased by testosterone therapy. However, testosterone therapy is contraindicated in the presence of active prostate cancer. In men over age 50 years, serum prostate-specific antigen (PSA) levels should be monitored before testosterone therapy as well as each year during therapy. Hypogonadal men who have had a prostatectomy for low-grade prostate cancer, and who have remained in complete remission for several years, may have testosterone therapy given cautiously while monitoring sensitive serum PSA levels.

Erythrocytosis develops in some men who are treated with testosterone. Erythrocytosis is more common with intramuscular injections of testosterone enanthate than with transcutaneous testosterone. It is particularly common in men receiving intramuscular testosterone enanthate in doses of 200 mg intramuscularly every 2 weeks. However, no increase in the incidence of thromboembolic events has been reported.

Testosterone therapy tends to aggravate sleep apnea in older men, likely through central nervous system effects. Surveillance for sleep apnea is recommended during testosterone therapy and a formal evaluation with nocturnal pulse oximetry recording is recommended for all high-risk patients. A man's risk for sleep apnea may be approximated by determining an "adjusted neck circumference" with the following algorithm: Measure the neck circumference in centimeters; add 4 cm if the patient is hypertensive; add 3 cm if the patient snores; add 3 cm if the patient chokes or gasps most nights. Adjusted neck circumference: < 43 = low risk; 43–48 = moderate risk; > 48 = high risk.

Men who are treated with testosterone frequently experience some increase in acne, which is usually mild and tolerated; topical antiacne therapy or a reduction in testosterone replacement dosage may be required. Increases in intraocular pressure have occurred during testosterone therapy. During the initiation of testosterone replacement therapy, gynecomastia develops in some men, which usually is mild and tends to resolve spontaneously; switching from testosterone injections to testosterone transdermal gel may help this condition.

Prognosis of Male Hypogonadism

If hypogonadism is due to a pituitary lesion, the prognosis is that of the primary disease (eg, tumor, necrosis). The prognosis for restoration of virility is good if testosterone is given.

Testicular Tumors in Adults

(See also Chapter 23: Urologic Disorders.)

About 95% of testicular tumors are germ cell tumors (seminomas or nonseminomas). Seminomas do not produce -fetoprotein, but about 5–10% produce some hCG. Nonseminomas, on the other hand, produce increased serum levels of one or both of these markers in about 90% of cases. Men with liver disease may have misleadingly high levels of -fetoprotein. Most germ cell tumors are sensitive to cisplatin-based combined chemotherapy. Sperm banking is advised.

About 5% of testicular tumors are Leydig or Sertoli cell tumors. Leydig cell tumors tend to produce estrogen (75%) and cause gynecomastia and impotence on that basis; they may sometimes produce androgens that can cause pseudoprecocious puberty in boys. Sertoli cell tumors may also produce estrogen (30%) with feminization; gynecomastia may be due to hCG secretion (25%).

Some testicular tumors may be small and nonpalpable yet may secrete sufficient amounts of hCG or estrogen to cause gynecomastia or impotence. Testicular ultrasound may help reveal small tumors.

After unilateral orchiectomy for testicular cancer, an elevated FSH level prior to further treatment indicates a patient at higher risk for cancer in the remaining testis.

Cryptorchism

One or both testes may be absent from the scrotum at birth in about 20% of premature or low-birth-weight male infants and in 3–6% at full term infants. Cryptorchism is found in 1–2% of males after 1 year of age but must be distinguished from retractile testes, which require no treatment. Cryptorchism should be corrected before age 12–24 months in an attempt to reduce the risk of infertility, which occurs in up to 75% of men with bilateral cryptorchism and in 50% of men with unilateral cryptorchism. It is not clear, however, whether such early orchiopexy improves ultimate fertility. Some patients have underlying hypogonadism.

The ultimate incidence of significant testicular neoplasia is about 0.002% in normal males, 0.06% in cryptorchid males, and up to 5% in patients with intra-abdominal testes.

If the testes are not palpable, ultrasound or MRI can be used to locate them. Alternatively, hCG, 1500 units intramuscularly daily for 3 days, causes a significant rise in testosterone if the testes are present. Therapy with hCG results in a testicular descent rate of about 25%.

Orchiopexy decreases the risk of neoplasia when performed before 10 years of age. Orchiectomy after puberty is an option for intra-abdominal testes.

Gynecomastia

Essentials of Diagnosis

- Enlargement of the male breast, often asymmetric or unilateral.
- Glandular gynecomastia characterized by tenderness.
- Fatty gynecomastia typically nontender.
- Must be distinguished from tumors or mastitis.

General Considerations

Gynecomastia refers to a female-appearing male breast. Pubertal gynecomastia is common and the swelling usually subsides spontaneously within a year. Gynecomastia is particularly common in teenagers who are very tall or overweight. Gynecomastia develops in about 50% of athletes who abuse androgens and anabolic steroids. It is seen in Klinefelter syndrome, which affects 1:500 men. (See section on Klinefelter syndrome.) Gynecomastia can develop in HIV-infected patients treated with highly active antiretroviral therapy (HAART), especially in men receiving efavirenz or didanosine; breast enlargement resolves spontaneously in 73% of patients within 9 months. Gynecomastia is common among elderly men, particularly when there is associated weight gain. However, it can be the first sign of a serious disorder. Patients with Peutz–Jeghers syndrome are prone to development of gynecomastia caused by testicular tumors.

The causes of gynecomastia are multiple and diverse (Table 26–14).

Clinical Findings

Symptoms and Signs

Gynecomastia is graded according to severity: I, mild; II, moderate; III, severe. Fatty gynecomastia is usually diffuse and nontender. Glandular enlargement beneath the areola may be tender. Pubertal gynecomastia is characterized by tender discoid enlargement of breast tissue 2–3 cm in diameter beneath the areola.

Laboratory Findings

Laboratory measurements of plasma levels of PRL (see Hyperprolactinemia) and the -subunit of hCG (-hCG). Detectable levels of -hCG implicate a testicular tumor (germ cell or Sertoli cell) or other malignancy (usually lung or liver). Detectable low levels of serum -hCG (< 5 mU/mL) may be reported in men with primary hypogonadism and high serum LH levels if the assay for -hCG cross-reacts with LH. Measurements of plasma testosterone and LH are valuable in the diagnosis of primary or secondary hypogonadism. A low testosterone and high LH are seen in primary hypogonadism. High testosterone levels plus high LH levels characterize partial androgen resistance. Serum estradiol is determined but is usually normal; increased levels may result from testicular tumors, increased -hCG, liver disease, obesity, adrenal tumors (rare), true hermaphroditism (rare), or gain of function mutations affecting the aromatase gene (rare). Many estrogens and substances with estrogenic activity are not detected by estradiol assays. Serum TSH (sensitive) and FT_4 levels are also determined. A karyotype (for Klinefelter syndrome) is obtained in men with persistent gynecomastia without obvious cause.

Investigation of unclear cases should include a chest radiograph to search for metastatic or bronchogenic carcinoma. Needle biopsy with cytologic examination may be performed on suspicious areas of male breast enlargement (especially when unilateral or asymmetric) to distinguish gynecomastia from tumor or mastitis.

Treatment

Pubertal gynecomastia often resolves spontaneously within 1–2 years. Drug-induced gynecomastia resolves after the offending drug is removed. Spironolactone can be stopped, with substitution of a selective aldosterone antagonist such as eplerenone. Patients with painful or persistent (> 12 months) gynecomastia may be treated with a 3- to 9-month course of a SERM (eg, raloxifene or tamoxifen). SERM therapy is much more effective for glandular ("lumpy") gynecomastia than for diffuse fatty gynecomastia. There is some evidence that raloxifene, taken orally in a dose of 60 mg daily, may be the more effective drug. Aromatase inhibitors (eg, letrozole, anastrozole, or exemestane) are marginally effective and should not ordinarily be used for adolescent boys, since long-term therapy may prevent epiphyseal fusion. Surgical correction is reserved for patients with persistent or severe gynecomastia, since results are often disappointing. Endoscopically assisted transaxillary liposuction and subcutaneous mastectomy may produce acceptable results. Generally, it is prudent to treat patients for gynecomastia only when it becomes a troubling and continuing problem for them.

Martinez J et al. An unusual case of gynecomastia associated with soy product consumption. Endocr Pract. 2008 May–Jun;14(4):415–8. [PMID: 18558591]

Primary Amenorrhea

(See also Chapter 18: Gynecologic Disorders.) Menarche ordinarily occurs between ages 11 and 15 years (average in the United States: 12.7 years). The failure of any menses to appear is termed "primary amenorrhea," and evaluation is commenced (1) at age 14 years if neither menarche nor breast development has occurred or if height is in the lowest 3%, or (2) at age 16 years if menarche has not occurred.

Etiology

The causes of primary amenorrhea include hypothalamic-pituitary causes, hyperandrogenism, ovarian causes, pseudohermaphroditism, uterine causes, and pregnancy.

Hypothalamic-Pituitary Causes (With Low or Normal FSH)

A genetic deficiency of GnRH and gonadotropins may be isolated or associated with other pituitary deficiencies or diminished olfaction (Kallmann syndrome). Hypothalamic lesions, particularly craniopharyngioma, may be present. Pituitary tumors may be nonsecreting or may secrete PRL or GH. Cushing syndrome may be caused by corticosteroid treatment, a cortisol-secreting adrenal tumor, or an ACTH-secreting pituitary tumor. Hypothyroidism can delay adolescence. Head trauma or encephalitis can cause gonadotropin deficiency. Primary amenorrhea may also be caused by constitutional delay of adolescence, organic illness, vigorous exercise (eg, ballet dancing, running), stressful life events, dieting, or anorexia nervosa; however, these conditions should not be assumed to account for amenorrhea without a full physical and endocrinologic evaluation. (See section on Hypopituitarism.)

Hyperandrogenism (With Low or Normal FSH)

Excess testosterone may be secreted by adrenal tumors or by adrenal hyperplasia caused by steroidogenic enzyme defects such as P450c21 deficiency (salt-wasting) or P450c11 deficiency (hypertension). Ovarian tumors or polycystic ovaries may also secrete excess testosterone. Androgenic steroids may also cause this syndrome.

Ovarian Causes (With High FSH)

Gonadal dysgenesis (Turner syndrome and variants; see below) is a frequent cause of primary amenorrhea. Ovarian failure due to autoimmunity is a common cause. Rare deficiencies in certain ovarian steroidogenic enzymes are causes of primary hypogonadism without virilization: 3 -hydroxysteroid dehydrogenase deficiency (adrenal insufficiency with low serum 17-hydroxyprogesterone) and P450c17 deficiency (hypertension and hypokalemia with high serum 17-hydroxyprogesterone). A whole-body deficiency in P450 aromatose (P450arom) activity produces female hypogonadism associated with polycystic ovaries, tall stature, osteoporosis, and virilization.

Pseudohermaphroditism (With High LH)

An enzymatic defect in testosterone synthesis may present as a sexually immature phenotypic girl with primary amenorrhea. Complete androgen resistance (testicular feminization) presents as a phenotypic young woman without sexual hair but with normal breast development and primary amenorrhea. In both cases, the uterus is absent and testes are intraabdominal or cryptorchid. Intraabdominal testes are surgically resected. Such patients are treated as normal but infertile, hypogonadal women.

Uterine Causes (With Normal FSH)

Congenital absence or malformation of the uterus may be responsible for primary amenorrhea, as may an unresponsive or atrophic endometrium. An imperforate hymen is occasionally the reason for the absence of visible menses.

Pregnancy (With High hCG)

Pregnancy may be the cause of primary amenorrhea even when the patient denies ever having had sexual intercourse.

Clinical Findings

Symptoms and Signs

Patients with primary amenorrhea require a thorough history and physical examination to look for signs of the conditions noted above. Headaches or visual field abnormalities implicate a hypothalamic or pituitary tumor. Signs of pregnancy may be present. Blood pressure abnormalities, acne, and hirsutism should be noted. Short stature may be seen with an associated GH or thyroid hormone deficiency. Short stature with manifestations of gonadal dysgenesis indicates Turner syndrome (see below). Olfaction testing screens for Kallmann syndrome. Obesity and short stature may be signs of Cushing syndrome. Tall stature may be due to eunuchoidism or gigantism. Hirsutism or virilization suggests excessive testosterone.

An external pelvic examination plus a rectal examination should be performed to assess hymenal patency and the presence of a uterus.

Laboratory Findings

The initial endocrine evaluation should include serum determinations of FSH, LH, PRL, testosterone, TSH, FT_4, and hCG (pregnancy test). Patients who are virilized or hypertensive require serum electrolyte determinations and further hormonal evaluation. Girls with low-normal FSH and LH—especially those with high PRL levels—are evaluated by MRI of the hypothalamus and pituitary. Girls who have a normal uterus and high FSH without the classic features of Turner syndrome may require a karyotype to diagnose X chromosome mosaicism.

Treatment

Treatment of primary amenorrhea is directed at the underlying cause. Girls with permanent hypogonadism are treated with ERT (see under Secondary Amenorrhea & Menopause).

Torstveit MK et al. Participation in leanness sports but not training volume is associated with menstrual dysfunction: a national survey of 1276 elite athletes and controls. Br J Sports Med. 2005 Mar;39(3):141–7. [PMID: 15728691]

Secondary Amenorrhea & Menopause

Secondary amenorrhea is defined as the absence of menses for 3 consecutive months in women who have passed menarche. Menopause is defined as the terminal episode of naturally occurring menses; it is a retrospective diagnosis, usually made after 6 months of amenorrhea.

Etiology

The causes of secondary amenorrhea include pregnancy, hypothalamic-pituitary causes, hyperandrogenism, uterine causes, premature ovarian failure, and menopause.

Pregnancy (High hCG)

Pregnancy is the most common cause for secondary amenorrhea in women of childbearing age. The differential diagnosis includes rare ectopic secretion of hCG by a choriocarcinoma or bronchogenic carcinoma.

Hypothalamic-Pituitary Causes (With Low or Normal FSH)

The hypothalamus must release GnRH in a pulsatile manner for the pituitary to secrete gonadotropins. GnRH pulses occurring more than once per hour favor LH secretion, while less frequent pulses favor FSH secretion. In normal ovulatory cycles, GnRH pulses in the follicular phase are rapid and favor LH synthesis and ovulation; ovarian luteal progesterone is then secreted that slows GnRH pulses, causing FSH secretion during the luteal phase. Most women with hypothalamic amenorrhea have a persistently low frequency of GnRH pulses.

Secondary "hypothalamic" amenorrhea may be caused by stressful life events such as school examinations or leaving home. Such women usually have a history of normal sexual development and irregular menses since menarche. Amenorrhea may also be the result of strict dieting, vigorous exercise, organic illness, or anorexia nervosa. Intrathecal infusion of opioids causes amenorrhea in most women. These conditions should not be assumed to account for amenorrhea without a full physical and endocrinologic evaluation. Young women in whom the results of evaluation and progestin withdrawal test are normal have noncyclic secretion of gonadotropins resulting in anovulation. Such women typically recover spontaneously but should have regular evaluations and a progestin withdrawal test about every 3 months to detect loss of estrogen effect.

PRL elevation due to any cause (see section on hyperprolactinemia) may cause amenorrhea. Pituitary tumors or other lesions may cause hypopituitarism. Corticosteroid excess of any cause suppresses gonadotropins.

Hyperandrogenism (With Low-Normal FSH)

Elevated serum levels of testosterone can cause hirsutism, virilization, and amenorrhea. In PCOS, GnRH pulses are persistently rapid, favoring LH synthesis with excessive androgen secretion; reduced FSH secretion impairs follicular maturation. Progesterone administration can slow the GnRH pulses, thus favoring FSH secretion that induces follicular maturation. Rare causes include adrenal P450c21 deficiency, ovarian or adrenal malignancies, ectopic ACTH secretion by a malignancy, and Cushing disease. Anabolic steroids also cause amenorrhea.

Uterine Causes (With Normal FSH)

Infection of the uterus commonly occurs following delivery or D&C but may occur spontaneously. Endometritis due to tuberculosis or schistosomiasis should be suspected in endemic areas. Endometrial scarring may result, causing amenorrhea (Asherman syndrome). Such women typically continue to have monthly premenstrual symptoms. The vaginal estrogen effect is normal.

Premature Ovarian Failure (With High FSH)

This refers to primary hypogonadism that occurs before age 40 years. It affects about 1% of women. About 30% of such cases are due to autoimmunity against the ovary. About 8% of cases are due to X chromosome mosaicism. Other causes include surgical bilateral oophorectomy, radiation therapy for pelvic malignancy, and chemotherapy. Women who have undergone hysterectomy are prone to premature ovarian failure even though the ovaries were left intact. Myotonic dystrophy, galactosemia, and mumps oophoritis are additional causes. Other cases may be familial or idiopathic. Ovarian failure is usually irreversible.

Menopause (With High FSH)

"Climacteric" is defined as the period of natural physiologic decline in ovarian function, generally occurring over about 10 years. By about age 40 years, the remaining ovarian follicles are those that are the least sensitive to gonadotropins. Increasing titers of FSH are required to stimulate estradiol secretion. Estradiol levels may actually rise during early climacteric.

The normal age for menopause in the United States ranges between 48 and 55 years, with an average of about 51.5 years. Serum estradiol levels fall and the remaining estrogen after menopause is estrone, derived mainly from peripheral aromatization of adrenal androstenedione. Such peripheral production of estrone is enhanced by obesity and liver disease. Individual differences in estrone levels partly explain why the symptoms noted above may be minimal in some women but severe in others.

Clinical Findings

Symptoms and Signs

All women with amenorrhea require a complete history and physical examination. Nausea and breast engorgement are typical signs of early pregnancy. Headache or visual field abnormalities are seen with pituitary or hypothalamic tumors. Complaints of thirst and polyuria require evaluation; diabetes insipidus implicates a hypothalamic lesion. Goiter may be due to hyperthyroidism. Weight loss, diarrhea, or skin darkening may indicate adrenal insufficiency. Weight loss with a distorted body image implicates anorexia nervosa. The breasts are examined carefully for galactorrhea, a common sign of hyperprolactinemia. Hirsutism or virilization may be a sign of hyperandrogenism.

Manifestations of hypercortisolism (eg, weakness, psychiatric changes, hypertension, central obesity, hirsutism, thin skin, ecchymoses) may indicate alcoholism or Cushing syndrome. Signs of acromegaly or gigantism may also indicate a pituitary tumor. Signs of systemic illness (eg, cirrhosis, kidney disease) should be appreciated. Various drugs may elevate PRL and cause amenorrhea (see section on Hyperprolactinemia). Needle tracks may indicate heroin or amphetamine abuse.

Psychological symptoms of "climacteric" may include depression and irritability. Women may experience fatigue, insomnia, headache, diminished libido, or rheumatologic symptoms. Vasomotor instability (hot flushes) is experienced by 80% of women, lasting seconds to many minutes. Hot flushes with drenching sweats may be most severe at night or may be triggered by emotional stress. Some women continue to menstruate for many months despite symptoms of estrogen deficiency. The acute symptoms of estrogen deficiency noted above tend to decline in severity within several years after menopause. However, about 35% of women have symptoms for more than 5 years. The late manifestations of estrogen deficiency include urogenital atrophy with vaginal dryness and dyspareunia; dysuria, frequency, and incontinence may occur. Increased bone osteoclastic activity increases the risk for osteoporosis and fractures. The skin becomes more wrinkled. Increases in the

LDL:HDL cholesterol ratio cause an increased risk for arteriosclerosis.

A careful pelvic examination is always required to check for uterine or adnexal enlargement and to obtain a Papanicolaou smear and a vaginal smear for assessment of estrogen effect (see illustration). Various life stresses, vigorous exercise, and "crash" dieting all predispose to amenorrhea; however, such factors should not be assumed to account for amenorrhea without a complete workup to screen for other causes.

Fig.

Patterns formed when cervical mucus is smeared on a slide, permitted to dry, and examined under the microscope. Progesterone makes the mucus thick and cellular. In the smear from a patient who failed to ovulate (bottom), there is no progesterone to inhibit the estrogen-induced fern pattern. Laboratory Findings

Since pregnancy is the most common cause of amenorrhea, women of childbearing age are immediately screened with a serum or urine hCG (pregnancy test). An elevated hCG overwhelmingly indicates pregnancy; false-positive testing may occur very rarely with ectopic hCG secretion (eg, choriocarcinoma or bronchogenic carcinoma). Women without an elevated hCG receive further laboratory evaluation including serum PRL, FSH, LH, TSH, and plasma potassium. Hyperprolactinemia or hypopituitarism (without obvious cause; see section on Hypopituitarism) should prompt an MRI study of the pituitary region. Routine testing for kidney and liver function (eg, BUN, serum creatinine, bilirubin, alkaline phosphatase, and alanine aminotransferase) is also performed. A serum testosterone level is obtained in hirsute or virilized women. Patients with manifestations of hypercortisolism receive a 1-mg overnight dexamethasone suppression test for initial screening (see section on Cushing syndrome). Nonpregnant women without any laboratory abnormality may receive a 10-day course of a progestin (eg, medroxyprogesterone acetate, 10 mg/d); absence of withdrawal menses typically indicates a lack of estrogen or a uterine abnormality.

Treatment

Therapy of symptomatic hypogonadism generally consists of ERT (see below). Slow, deep breathing can ameliorate hot flushes. For women with severe hot flushes who cannot take estrogen, gabapentin is quite effective in oral doses titrated up to 800 mg every 8 hours; gabapentin is frequently associated with side effects such as fatigue, headache, dizziness, and cognitive impairment. Tamoxifen and raloxifene offer bone protection but aggravate hot flushes. Treatment or prevention of postmenopausal osteoporosis with bisphosphonates such as alendronate, risedronate, or intravenous zoledronic acid (see section on Osteoporosis) is another therapeutic option. Women with low serum testosterone levels may experience hypoactive sexual desire disorder (HSDD) that may respond to low-dose testosterone replacement.

Estrogen Replacement Therapy

The Women's Health Initiative (WHI) monitored 16,606 postmenopausal women in the United States in a prospective, double-blinded, placebo-controlled study of postmenopausal HRT. A control group of women taking a daily placebo was compared with (1) women receiving daily conventional-dose oral combined HRT (conjugated equine estrogens [CEE] 0.625 mg/d with medroxyprogesterone acetate [MPA] 2.5 mg/d) and (2) women, having had a hysterectomy, receiving only CEE 0.625 mg/d.

The WHI risk–benefit findings (described below) have dramatically changed postmenopausal HRT. To reduce the risks of HRT, lower-dose estrogen regimens are preferred over conventional-dose therapy. Estrogen preparations other than CEE are increasingly favored. Transdermal and vaginal estrogen preparations are widely preferred over oral estrogen replacement. Also, the potential adverse effects of progestins are now recognized, such that women taking very low-dose estrogen replacement may receive progestin therapy only periodically, if at all. For moderate to high-dose estrogen therapy, progestins are being used in lower doses. Also, clinicians are now tending to prescribe progestins other than MPA or progesterone-eluting intrauterine devices. **Oral estrogen preparations** include CEEs (0.3, 0.45, 0.625, 0.9, and 1.25 mg), ethinyl estradiol (20 and 50 mcg), estradiol (0.5, 1, 1.5, and 2 mg), estropipate (0.75, 1.5, 3, and 6 mg), plant-derived esterified estrogens (eg, Menest, Estratab, 0.3, 0.625, and 2.5 mg), and synthetic estrogens (eg, Cenestin, 0.3, 0.625, 0.9, and 1.25 mg).

Oral estrogen plus progestin preparations include CEE with MPA (Prempro 0.3/1.5, 0.45/1.5, 0.625/2.5, and 0.625/5), CEE for 14 days cycled with CEE plus MPA for 14 days (Premphase 0.625, 0.625/5), estradiol with norethindrone acetate (Activella 1/0.5), ethinyl estradiol with norethindrone acetate (Femhrt 1/5, 5 mcg/1 mg/tablet), and estradiol with norgestimate (Ortho-Prefest, sequences of estradiol 1 mg/d for 3 days, alternating with a combination of 1 mg estradiol/0.09 mg norgestimate daily for 3 days). Oral contraceptives can also be used for combined HRT.

Transdermal estradiol: Estradiol can be delivered systemically with different transdermal systems. Because transdermal absorption of estradiol is somewhat variable, this delivery method will not work for all women.

1. Transdermal systems with estradiol mixed with adhesive: These systems tend to cause minimal skin irritation. Of the following preparations, the Vivelle-Dot patches are the smallest and least obtrusive. Available preparations include Esclim, Vivelle, and Vivelle-Dot (0.025, 0.0375, 0.05, 0.075, or 0.1 mg/d), replaced twice weekly; Alora (0.025, 0.05, 0.075, or 0.1 mg/d), replaced twice weekly; and Climara (0.025, 0.0375, 0.05, 0.06, 0.075, or 0.1 mg/d), replaced weekly; FemPatch (0.025 mg/d), replaced weekly; and Menostar (0.014 mg/d), replaced weekly. This type of estradiol skin patch can be cut in half and applied to the skin without proportionately greater loss of potency.

2. Transdermal systems with estradiol in a drug reservoir: These systems cause significant skin irritation in some women. Available preparations include Estraderm (0.05 or 0.1 mg/d), replaced twice weekly.

3. Transdermal systems with estradiol (E) and norethindrone acetate (NA) mixed with adhesive:

Available preparations include Combipatch (0.05 mg/d E and 0.14 mg/d NA, or 0.05 mg/d E and 0.25 mg/d NA), replaced twice weekly. The addition of a progestin increases the likelihood of side effects compared with therapy with estrogen alone.

4. 4. Transdermal estradiol gel (EstroGel, 0.6%) is available in a metered-dose dispenser that delivers 1.25 g estradiol per actuation. The gel is applied to one arm from the wrist to the shoulder daily after bathing. To avoid spreading the estradiol to others, the hands should be washed and precautions taken to avoid prolonged skin contact with children. Application of sunscreen prior to estradiol gel has been reported to *increase* the transdermal absorption of estradiol.

Vaginal estrogen: Urogenital atrophy commonly develops in postmenopausal women and can cause dryness of the vagina, genital itching, burning, and dyspareunia. Urinary symptoms can include urgency and dysuria. Vaginal estrogen is intended to deliver estrogen directly to local tissues in an effort to reduce these symptoms, while minimizing systemic estrogen exposure. Some estrogen is absorbed systemically and can relieve menopausal symptoms. Systemically absorbed estrogen avoids first-pass liver metabolism, causing less hypertriglyceridemia and prothrombotic effects than oral estrogen. Manufacturers recommend that these preparations be used for only 3–6 months in women with an intact uterus, since vaginal estrogen can cause endometrial proliferation. However, most clinicians use them for longer periods. Vaginal estrogen can be administered in three different ways:

1. Estrogen vaginal creams: These creams are administered intravaginally with a measured-dose applicator daily for 2 weeks for atrophic vaginitis, then administered one to three times weekly. Available preparations include CEEs (Premarin, 0.626 mg/g cream), 0.25–0.5 g cream vaginally; dienestrol (Ortho Dienestrol, 10 mg/g cream), 0.25–0.5 g cream vaginally; estradiol (Estrace, 0.1 mg/g cream), 1 g cream vaginally; and estropipate (Ogen, 1.5 mg/g cream), 0.25–0.5 g vaginally.

2. Estradiol vaginal tablets: These tablets are sold prepackaged in a disposable applicator and can be administered deep intravaginally daily for 2 weeks for atrophic vaginitis, then twice weekly. The tablets dissolve into a gel that gradually releases estradiol. Available preparations include vaginal estradiol tablets (Vagifem, 25 mcg/tablet).

3. Estradiol vaginal rings: These rings are inserted manually into the upper third of the vagina, worn continuously, and replaced every 90 days. Only a small amount of the released estradiol enters the systemic circulation. Vaginal rings do not usually interfere with

sexual intercourse. If a ring is removed or descends into the introitus, it may be washed in warm water and reinserted. Available preparations include Estring (2 mg estradiol/ring, releasing 0.0075 mg/d) and Femring (12.4 mg estradiol/ring, releasing 0.05 mg/d, or 24.8 mg estradiol/ring, releasing 0.10 mg/d).

Oral progestins: For a woman with an intact uterus, long-term conventional-dose unopposed systemic estrogen therapy can cause endometrial hyperplasia, which typically results in DUB and can rarely lead to endometrial cancer. Progestin therapy transforms proliferative into secretory endometrium, causing a menses when given intermittently or no bleeding when given continuously.

The type of progestin preparation, its dosage, and the timing of administration may be tailored to the given situation. Progestins may be given daily, monthly, or at longer intervals. When given episodically, progestins are usually administered for 7–14 day periods. Progestins are available in different formulations: Micronized progesterone (Prometrium, 100 mg/capsule), medroxyprogesterone acetate (Provera, Amen, Cycrin; 2.5, 5.0, and 10 mg/scored tablet), norethindrone acetate (Aygestin, 5 mg/tablet), and norethindrone (Micronor, Nor-QD; 0.35 mg/tablet).

Topical progesterone (20–50 mg/d) may reduce hot flushes in women who are intolerant to oral HRT. It may be applied to the upper arms, thighs, or inner wrists daily. It may be compounded as micronized progesterone 250 mg/mL in a transdermal gel. Its effects upon the breast and endometrium are unknown.

Progesterone-releasing intrauterine devices: Progesterone-releasing intrauterine devices can be useful for women receiving ERT, since they can reduce the incidence of DUB and endometrial carcinoma without exposing women to the significant risks of systemic progestins.

Benefits of ERT: Estrogen replacement without progestin (unopposed): Surprisingly, the WHI study found that postmenopausal women who received conventional-dose estrogen-only therapy had a reduced risk for breast cancer (seven fewer cases/year per 10,000 women) compared with a placebo group. The WHI study also found that women who received estrogen therapy experienced a reduced number of hip fractures (six fewer fractures/year per 10,000 women) compared with placebo. In the WHI study, unopposed estrogen therapy had no discernible effect upon the risk for heart attacks, colorectal cancer, or overall mortality. A 20-year study of 8801 women living in a retirement community found that estrogen use was associated with improved survival. Age-adjusted mortality rates were 56.4 (per 1000 person-years) among nonusers and 50.4 among women who had used estrogen for 15 years or longer.

Women receiving unopposed conventional-dose daily conjugated estrogen and medroxyprogesterone acetate (0.625 mg and 2.5 mg, respectively) for an average of 5.6 years, experienced a lower risk of developing diabetes (3.5%) versus those taking a placebo (4.2%).

Serum levels of atherogenic lipoprotein(a) are reduced by estrogen replacement with or without daily or cycled progestins. Improvement in serum HDL cholesterol is greatest with unopposed estrogen but is also seen with the addition of a progestin.

Estrogen replacement improves or eliminates postmenopausal hot flushes and diaphoretic episodes. Vaginal moisture is improved. Libido is enhanced in some women. Sleep disturbances are common in menopause and can be reversed with estrogen replacement. Sex hormone replacement may also improve the body pain and reduced physical function experienced by some women at the time of menopause.

Perimenopause-related depression is improved by unopposed estrogen replacement; the addition of a progestin may negate this effect. Estrogen replacement, when initiated at the time of menopause or oophorectomy, has been reported to help protect cognitive function, particularly verbal memory, whereas estrogen replacement that is begun many years after menopause confers little or no benefit on cognition. Estrogen therapy does not appear to reduce the risk of Alzheimer dementia.

Unopposed estrogen replacement improves glycemic control in women with type 2 diabetes mellitus. Estrogen replacement does not prevent facial skin wrinkling; however, it may improve facial skin moisture and thickness, reducing seborrhea and atrophy.

Risks of ERT: The risks of estrogen replacement depend on the dose. Conventional doses (eg, oral conjugated estrogens 0.625 mg/d or transdermal estradiol 0.05 mg/d) carry higher risks than lower doses (eg, oral conjugated estrogens, 0.3 mg/d or transdermal estradiol 0.025 mg/d). Route of administration also affects risks, since oral estrogens pass through the liver and increase hepatic production of clotting factors (thereby increasing the risks of thrombotic stroke), whereas transdermal or vaginal administration of estrogen does not significantly increase clotting proclivity. The risks for HRT also depend on whether estrogen is administered alone (unopposed HRT) or with a progestin (combined HRT).

Estrogen replacement without progestin (unopposed HRT): Conventional-dose unopposed estrogen replacement increases the risk of endometrial hyperplasia and DUB, which often prompts patients to stop the estrogen. Lower-dose unopposed estrogen has a much lower risk of DUB. Recurrent dysfunctional bleeding necessitates a pelvic examination and possibly an endometrial biopsy.

Unopposed estrogen in conventional doses may increase the risk for endometrial carcinoma, although the absolute risk remains low. A Cochrane Database Review found no increased risk of endometrial carcinoma in a review of 30 randomized controlled trials. Therefore, lower-dose unopposed estrogen replacement confers a negligible risk for endometrial cancer.

Long-term conventional-dose unopposed estrogen increases the mortality risk from ovarian cancer, although the absolute risk is small. The annual age-adjusted ovarian cancer death rates for women taking estrogen replacement for 10 years are 64:100,000 for current users, 38:100,000 for former users, and 26:100,000 for women who had never taken estrogen. Lower-dose estrogen replacement is believed to confer a negligible increased risk for ovarian cancer.

The WHI study has reported that conventional doses of unopposed oral estrogen do not increase the risk of breast cancer; in fact, somewhat fewer breast cancers were found in women taking estrogen alone, compared with placebo. However, the WHI trial was stopped in 2002 because of an increased risk of stroke among women taking conjugated oral estrogens in doses of 0.625 mg daily; the risk was about 44 strokes per 10,000 person-years versus about 32 per 10,000 person-years in women taking placebo. Transdermal or transvaginal estrogen is not expected to increase the risk of stroke.

Conventional-dose oral estrogen replacement increases the risk of deep venous thrombosis. It can cause hypertriglyceridemia, particularly in women with preexistent hyperlipidemia, rarely resulting in pancreatitis. Postmenopausal estrogen therapy also slightly increases the risk of gallstones and cholecystitis. Oral estrogens reduce the effectiveness of growth hormone replacement. These side effects can be reduced or avoided by using nonoral estrogen replacement.

Elderly women, receiving long-term conventional-dose estrogen replacement, experience an increased risk of urinary incontinence. Some women complain of estrogen-induced edema or mastalgia. Estrogen replacement has been reported to lower the seizure threshold in some women with epilepsy. Untreated large pituitary prolactinomas may enlarge if exposed to estrogen.

Estrogen replacement with a progestin (combined HRT): The WHI study found that women who received long-term conventional oral doses of combined HRT (conjugated estrogens 0.625 mg/d plus medroxyprogesterone acetate 2.5 mg/d) had an increased risk of deep venous thrombosis (3.5 per 1000 person-years) compared with women receiving placebo (1.7 per 1000 person-years).

Conventional-dose oral combined HRT results in an increased risk for myocardial infarction (24% or six additional heart attacks per 10,000 women), mostly in women with high-risk LDL levels or preexistent coronary disease. Most of the risk for myocardial infarction occurs in the first year of therapy. This increased risk is attributable to the progestin component, since the estrogen-only arm of the WHI study found no increased risk of myocardial infarction.

Long-term conventional-dose oral combined HRT increases breast density and increases the risk for abnormal mammograms (9.4% versus 5.4% for placebo). There is also a higher risk for breast cancer (8 cases per 10,000 women/year versus 6.5 cases per 10,000 women/year for placebo); no increased risk of breast cancer has been found with estrogen-only HRT. This increased risk for breast cancer appears to mostly affect relatively thin women with a BMI < 24.4. The Iowa Women's Health Study reported an increase in breast cancer with HRT only in women consuming more than 1 oz of alcohol weekly. No accelerated risk of breast cancer has been seen in users of HRT who have benign breast disease or a family history of breast cancer.

The Women's Health Initiative Mental Study (WHIMS) followed the effect of combined conventional-dose oral HRT on cognitive function in women 65–79 years old. HRT did not protect these older women from cognitive decline. In fact, they experienced an increased risk for severe dementia at a rate of 23 more cases/year for every 10,000 women over age 65 years.

In the WHI study, women receiving conventional-dose combined oral HRT experienced an increased risk of stroke (31 strokes per 10,000 women/year versus 26 strokes per 10,000 women/year for placebo). Stroke risk was also increased by hypertension, diabetes, and smoking.

Women taking combined estrogen–progestin replacement do not experience an increased risk of ovarian cancer. They do experience an increased risk of developing asthma.

Progestins may cause moodiness, particularly in women with a history of premenstrual dysphoric disorder. Cycled progestins may trigger migraines in certain women. Many other adverse reactions have been reported, including breast tenderness, alopecia, and fluid retention. Contraindications to the use of progestins include thromboembolic disorders, liver disease, breast cancer, and pregnancy.

SERMs (eg, raloxifene; Evista) are an alternative to estrogen replacement for hypogonadal women at risk for osteoporosis who prefer not to take estrogens because of their contraindications (eg, breast or uterine cancer) or side effects. Raloxifene does not reduce hot flushes, vaginal dryness, skin wrinkling, or breast atrophy; it does not improve cognition. However, in doses of 60 mg/d orally, it inhibits bone loss without stimulating effects upon the breasts or endometrium. Because raloxifene may slightly increase the risk of venous thromboembolism, it should not be used by women at prolonged bed rest or by those prone to thrombosis. In contrast with the use of ERT, concomitant progesterone therapy is not needed, and raloxifene does not increase the risk of development of breast cancer. Tibolone (Livial) is an SERM whose metabolites have mixed estrogenic, progestogenic, and weak androgenic activity. It is comparable to HRT for the treatment of climacteric-related complaints. It does not appear to significantly stimulate proliferation of breast or endometrial tissue. It depresses both serum triglycerides and HDL cholesterol. Long-term studies are lacking. It is not available in the United States.

Phytoestrogens are substances found in plants that bind to estrogen receptors. Phytoestrogens, found in soy and red clover extracts, do not appear to significantly improve menopausal hot flushes, cognitive function, bone density, or plasma lipids.

Testosterone replacement therapy in women: In premenopausal women, serum testosterone levels decline with age. Between 25 and 45 years of age, women's testosterone levels fall 50%. After natural menopause, the ovaries remain a significant source for testosterone. In fact, following natural menopause, serum testosterone levels do not fall abruptly and serum free testosterone levels may actually rise. In contrast, very low serum testosterone levels are found in women after bilateral oophorectomy, autoimmune ovarian failure, adrenalectomy, and hypopituitarism. Testosterone deficiency contributes to hot flushes, loss of sexual hair, muscle atrophy, osteoporosis, and diminished libido, also known as hypoactive sexual desire disorder (HSDD).

In women, diminished libido is common and multifactorial. Although low serum testosterone levels may contribute to HSDD, hysterectomy and sexual isolation are major causes. Low serum testosterone levels may also cause fatigue, a diminished sense of well-being, and a dulled enthusiasm for life. Androgen replacement may improve these problems.

Testosterone therapy is often effective, while DHEA therapy is not. Selected women may be treated with low-dose testosterone. Methyltestosterone can be taken orally in doses of 1.25–2.5 mg daily. Testosterone can also be compounded as a cream containing 1 mg/mL, with 1 mL applied to the low abdomen daily. Methyltestosterone is also available in combination with conjugated estrogens (eg, Estratest). This formulation is convenient but carries the same disadvantage as oral estrogen—increased risk of thromboembolism. Tablets contain either 1.25 mg conjugated estrogens with 2.5 mg methyltestosterone or 0.625 mg conjugated estrogens with 1.25 mg methyltestosterone. Estratest is usually started at the lowest strength. It should be given cyclically at the lowest dose that controls symptoms.

Women receiving testosterone therapy must be monitored for the appearance of any acne or hirsutism, and serum testosterone levels are determined periodically if women feel that they are benefitting and long-term testosterone therapy is instituted. Side effects of low-dose testosterone therapy are usually minimal but may include polycythemia, emotional changes hirsutism, acne, an adverse effect on lipids, and potentiation of warfarin anticoagulation therapy. Testosterone replacement tends to reduce both triglyceride and HDL cholesterol levels. Hepatocellular neoplasms and peliosis hepatis, rare complications of oral androgens at higher doses, have not been reported with methyltestosterone at lower doses of 2.5 mg orally daily. Androgens should not be given to women with liver disease or during pregnancy or breast-feeding. Testosterone replacement therapy for women should be used judiciously, since long-term prospective clinical trials are lacking. An analysis of the Nurses' Health Study found that women who had been taking CEEs plus methyltestosterone experienced an increased risk of breast cancer. Yearly mammography is recommended for all women over 40 years of age.

Turner Syndrome (Gonadal Dysgenesis)

Essentials of Diagnosis

- Short stature with normal growth hormone levels.
- Primary amenorrhea or early ovarian failure.
- Epicanthal folds, webbed neck, short fourth metacarpals.
- Renal and cardiovascular anomalies.

Turner syndrome comprises a group of X chromosome disorders that are associated with spontaneous abortion, primary hypogonadism, short stature, and other phenotypic anomalies. It affects 1–2% of fetuses, of which about 97% abort, accounting for about 10% of all spontaneous abortions. Nevertheless, it affects about 1 in every 2500 live female births. Patients with the classic syndrome (about 50% of cases) lack one of the two chromosomes (45,XO karyotype). Other patients with Turner syndrome have X chromosome abnormalities, such as ring X or Xq (X/abnormal X) or X chromosome deletions affecting all or some somatic cells (mosaicism, XX/XO).

Classic Turner Syndrome (45,XO Gonadal Dysgenesis)

Features of Turner's syndrome (Table 26–15) are variable and may be subtle in girls with mosaicism. Typical manifestations in adulthood include short stature, hypogonadism, webbed neck, high-arched palate, wide-spaced nipples, hypertension, and renal abnormalities. Emotional disorders are common.

Table 26–15. Manifestations of Turner syndrome.
Short stature
Distinctive facial features
Ptosis
Micrognathia

Low-set ears
Epicanthal folds
Sexual infantilism due to gonadal dysgenesis with primary amenorrhea (80%)
Early ovarian failure with secondary amenorrhea (20%)
Webbed neck (40%)
Low hairline
High-arched palate
Cubitus valgus
Short fourth metacarpals (50%)
Lymphedema of hands and feet (30%)
Hypoplastic widely spaced nipples
Hyperconvex nails
Pigmented nevi
Keloid formation (eg, surgical scars or after ear piercing)
Recurrent otitis media
Renal abnormalities (60%)
Horseshoe kidney
Hydronephrosis
Hypertension (idiopathic or due to coarctation or kidney disease)
Gastrointestinal disorders
Telangiectasis with bleeding

Celiac disease
Inflammatory bowel disease
Colon carcinoma
Liver disease
Impaired space-form recognition, direction sense, and mathematical reasoning
Cardiovascular anomalies
Coarctation of the aorta (10–20%)
Partial anomolous pulmonary venous connection
Bicuspid aortic valve (with aortic stenosis or insufficiency)
Aortic dissection due to coarctation and cystic medial necrosis of the aorta
Associated conditions
Obesity
Diabetes mellitus (types 1 and 2)
Dyslipidemia
Hyperuricemia
Hashimoto thyroiditis
Achlorhydria
Cataracts, corneal opacities
Neuroblastoma (1%)
Rheumatoid arthritis

Inflammatory bowel disease

Girls with Turner syndrome may be diagnosed at birth, since they tend to be small and may exhibit severe lymphedema. Evaluation for childhood short stature often leads to the diagnosis. Growth hormone and IGF-1 levels are normal. Hypogonadism presents as "delayed adolescence" (primary amenorrhea, 80%) or early ovarian failure (20%); girls with 45,XO Turner (blood karyotyping) who enter puberty are typically found to have mosaicism if other tissues are karyotyped. Hypogonadism is confirmed in girls who have high serum levels of FSH and LH. A blood karyotype showing 45,XO (or X chromosome abnormalities or mosaicism) establishes the diagnosis.

Treatment of short stature with daily injections of GH (0.1 unit/kg/d) plus an androgen (eg, oxandrolone) for at least 4 years before epiphysial fusion increases final height by a mean of about 10.3 cm over the mean predicted height of 144.2 cm. Such GH treatment rarely causes pseudotumor cerebri. After age 12 years, estrogen therapy is begun with low doses of conjugated estrogens (0.3 mg) or ethinyl estradiol (5 mcg) given on days 1–21 per month. When growth stops, HRT is begun with estrogen and progestin; transdermal estrogen may be used to initiate pubertal development.

Girls and women with Turner syndrome have an increased risk of aortic coarctation (11%) and bicuspid aortic valves (16%); these cardiac abnormalities are more common in patients with webbed necks. Bicuspid aortic valves are associated with an increased risk for infective endocarditis, aortic valvular stenosis or insufficiency, and ascending aortic aneurysm and dissection. Partial anomolous pulmonary vein connections occur in 13% and can lead to left-to-right shunting of blood. Adults with Turner syndrome have a high incidence of ECG abnormalities. Women with Turner's syndrome have a reduced life expectancy due in part to their increased risk for diabetes mellitus (types 1 and 2), hypertension, dyslipidemia, and osteoporosis.

Diagnostic vigilance and aggressive treatment of these conditions reduce the risk of aortic aneurysm dissection, ischemic heart disease, stroke, and fracture. Patients are prone to keloid formation after surgery or ear piercing. Yearly ocular examinations and periodic thyroid evaluations are recommended. It is advisable to evaluate all patients with Turner syndrome with an ultrasound, along with MRI examination of the chest and abdomen, looking for cardiac, aortic, and renal abnormalities. Repeat cardiovascular evaluations should be done every 3–4 years. Patients with the classic 45,XO karyotype have a high risk of renal structural abnormalities, whereas those with 46 X/abnormal X are more prone to malformations of the urinary collecting system. The risk of aortic dissection is increased more than 100-fold in women with Turner syndrome, particularly those with pronounced neck webbing and shield chest. Patients with aortic root enlargement are usually treated with -blockade and serial imaging. Women with Turner syndrome who are able to become pregnant are strongly advised to deliver via cesarean section due to the risk of aortic aneurysm rupture during vaginal delivery.

Turner Syndrome Variants

46,X (Abnormal X) Karyotype

Patients with small distal short arm deletions of the X chromosome (Xp-) that include the SHOX gene often have short stature and skeletal abnormalities but have a low risk of ovarian failure. Transmission of Turner syndrome from mother to daughter can occur. There may be an increased risk of trisomy 21 in the conceptuses of women with Turner syndrome. Patients with deletions of the long arm of the X chromosome (distal to Xq24) often have amenorrhea without short stature or other features of Turner syndrome. Abnormalities or deletions of other genes located on both the long and short arms of the X chromosome can produce gonadal dysgenesis with few other somatic features.

45,XO/46,XX Mosaicism

This karyotype results in a modified form of Turner syndrome. Such girls tend to be taller and may have more gonadal function and fewer other manifestations of Turner syndrome.

Other Variants

45,XO/46,XY mosaicism can produce some manifestations of Turner syndrome. Patients may have ambiguous genitalia or male infertility with an otherwise normal phenotype. Germ cell tumors, such as gonadoblastomas and seminomas, develop in about 10% of patients with 45,XO/46,XY mosaicism; most such tumors are benign.

Essentials of Diagnosis

- MEN 1: tumors of the parathyroid glands, endocrine pancreas and duodenum, pituitary, adrenal, thyroid; lipomas and facial angiofibromas.
- MEN 2A: medullary thyroid cancers, pheochromocytomas, Hirschsprung disease.
- MEN 2B: medullary thyroid cancers, pheochromocytomas, Marfan-like habitus, mucosal neuromas, intestinal ganglioneuroma, delayed puberty.

Syndromes of MEN are inherited as autosomal dominant traits and cause a predisposition to the development of tumors in different tissues, particularly involving endocrine glands (Table 26–16).

Table 26–16. Multiple endocrine neoplasia (MEN) syndromes: Incidence of tumor types.

Tumor Type	**MEN 1 (Wermer Syndrome)**	**MEN 2A (Sipple Syndrome)**	**MEN 2B**
Parathyroid	95%	20–50%	Rare
Pancreatic	54%		

Pituitary	42%		
Medullary thyroid carcinoma		> 90%	80%
Pheochromocytoma	Rare	20–35%	60%
Mucosal and gastrointestinal ganglioneuromas		Rare	> 90%
Subcutaneous lipoma	30%		
Adrenocortical adenoma	30%		
Thoracic carcinoid	15%		
Thyroid adenoma	55%		
Facial angiofibromas and collagenomas	85%		

MEN 1 (Wermer Syndrome)

MEN 1 is a familial multiglandular endocrine tumor syndrome, with a prevalence of 2–10 per 100,000 people. The presentation of MEN 1 is quite variable, even in the same kindred. Parathyroid, enteropancreatic, and pituitary tumors can be present in one individual, though not necessarily at the same time. Nonendocrine tumors also occur, such as subcutaneous lipomas, facial angiofibromas, and collagenomas. In some affected individuals, tumors may start developing in childhood, whereas in others, tumors develop late in adult life.

About 90% of patients with MEN 1 have germline mutations that are inherited as an autosomal dominant trait. Patients with MEN 1 usually have detectable mutations in the *menin* gene, located on the long arm of chromosome 11 (11q13). MEN 1 gene testing is available at a few centers and is able to detect the specific mutation in 60–95% of cases. If no mutation is detected, genetic linkage analysis can be done if there are several affected members in the kindred. Gene testing permits the rest of the kindred to be tested for the specific gene defect and allows informed genetic counseling.

With close endocrine surveillance of affected individuals, the initial biochemical manifestations (usually hypercalcemia) can often be detected as early as age 14–18 years in patients with a MEN 1 gene mutation, although clinical manifestations do not usually present until the third or fourth decade.

Hyperparathyroidism is the first clinical manifestation of MEN 1 in two-thirds of affected patients, but it may present at any time of life. Patients with the MEN 1 mutation have a > 90% lifetime risk of developing hyperparathyroidism. The hyperparathyroidism of MEN 1 is notoriously difficult to treat surgically, due to multiple gland involvement and the frequency of supernumerary glands and ectopic parathyroid tissue. Typically, three and one-half glands are resected, leaving one-half of the most normal-appearing gland intact. Also, during neck surgery, a thymectomy is performed to resect any intrathymic parathyroid glands or occult thymic carcinoid tumors. Nevertheless, the surgical failure rate is about 38%, and there is a recurrence rate of about 16%, with hypercalcemia often recurring many years after neck surgery. Aggressive parathyroid resection can cause permanent hypoparathyroidism. Patients with persistent or recurrent hyperparathyroidism should avoid oral calcium supplements and thiazide diuretics; oral therapy with calcimimetic drug, such as cinacalcet, is effective but expensive. The diagnosis and treatment of hyperparathyroidism is described earlier in this chapter.

Enteropancreatic tumors occur in about 75% of patients with MEN 1. **Nonsecretory neuroendocrine tumors** occur and do not secrete hormones; they tend to be large and very aggressive. **Gastrinomas** occur in about 35% of patients with MEN 1; they secrete gastrin, thereby causing severe gastric hyperacidity (Zollinger–Ellison syndrome) with peptic ulcer disease or diarrhea. Concurrent hypercalcemia, due to hyperparathyroidism (see above), stimulates gastrin and gastric acid secretion; control of the hypercalcemia often reduces gastric acid secretion and serum gastrin levels. These gastrinomas tend to be small, multiple, and ectopic; they are frequently found outside the pancreas, usually in the duodenum.

Gastrinomas of MEN 1 can metastasize to the liver; but in patients with MEN 1, depending upon the kindred, hepatic metastases tend to be less aggressive than those from sporadic gastrinomas. Treatment of patients with gastrinomas in MEN 1 is usually conservative, utilizing long-term high-dose proton pump inhibitor therapy and control of hypercalcemia; surgery is palliative and usually reserved for aggressive gastrinomas and those tumors arising in the duodenum. Zollinger–Ellison syndrome is also discussed in Chapter 15: Gastrointestinal Disorders.

Insulinomas cause hyperinsulinism and fasting hypoglycemia. They occur in about 15% of patients with MEN 1. Surgery is usually attempted, but the tumors can be small, multiple, and difficult to detect. The diagnosis and treatment of insulinomas are described in Diabetes Mellitus and Hypoglycemia. Glucagonomas (1.6%) secrete glucagon and cause diabetes and migratory necrolytic erythema. VIPomas (1%) secrete VIP and cause profuse watery diarrhea, hypokalemia, and achlorhydria (WDHA, Verner–Morrison syndrome). Somatostatinomas (0.7%) can cause diabetes mellitus, steatorrhea, and cholelithiasis.

Pituitary adenomas occur in about 42% of patients with MEN 1. They are more common in women (50%) than men (31%) and are the presenting tumor in 17% of patients with MEN 1. These tumors tend to be more aggressive macroadenomas (> 1 cm diameter, 85%) compared to sporadic pituitary tumors (42%). Of MEN 1-associated pituitary tumors, about 62% secrete PRL, 8% secrete GH, 13% secrete both PRL and GH, and 13% are nonsecretory; only 4% secrete ACTH and cause Cushing disease. The diagnosis and treatment of pituitary tumors and Cushing disease were described earlier in this chapter. These pituitary tumors can produce local pressure effects and hypopituitarism.

Adrenal adenomas or **hyperplasia** occurs in about 37% of patients with MEN 1 and 50% are bilateral. They are generally benign and nonfunctional. In one series, one out of 12 of these patients developed a feminizing adrenal carcinoma. These adrenal lesions are pituitary independent.

Nonendocrine tumors occur commonly in MEN 1. Small facial angiofibromas and subcutaneous lipomas are common. Collagenomas can present as firm dermal nodules. Malignant melanomas have been reported.

The differential diagnosis of MEN 1 includes sporadic or familial tumors of the pituitary, parathyroids, or pancreatic islets. Hypercalcemia (from any cause) may cause gastrointestinal symptoms and increased gastrin levels, simulating a gastrinoma. Routine suppression of gastric acid secretion with H_2-blockers or proton pump inhibitors causes a physiologic increase in serum gastrin that can be mistaken for a gastrinoma. H_2-blockers and metoclopramide cause hyperprolactinemia, simulating a pituitary prolactinoma.

Variants of MEN 1 also occur. Kindreds with MEN 1 Burin variant have a high prevalence of prolactinomas, late-onset hyperparathyroidism, and carcinoid tumors, but rarely enteropancreatic tumors.

MEN 2A (Sipple Syndrome)

MEN 2A is a rare familial multiglandular syndrome that is inherited as an autosomal dominant trait. Patients with MEN 2A should have genetic testing for a *ret* protooncogene (RET) mutation. Their first-degree relatives may then be tested for the specific RET mutation. Patients with MEN 2A may have **medullary thyroid carcinoma** (> 90%); hyperparathyroidism (20–50%), due to hyperplasia or multiple adenomas in over 70% of cases; **pheochromocytomas** (20–35%), which are often bilateral; or **Hirschsprung disease**. The medullary thyroid carcinoma is of mild to moderate aggressiveness. Children harboring an MEN 2A RET gene mutation are advised to have a prophylactic total thyroidectomy by age 6 years.

Siblings or children of patients with MEN 2A should have genetic testing to determine if they have a mutation of the ***ret*** protooncogene (RET) on chromosome 10cen-10q11.2; this identifies about 95% of affected individuals.

Each kindred has a certain *ret* codon mutation that correlates with the particular variation in the MEN 2 syndrome, such as the age of onset and aggressiveness of medullary thyroid cancer. The specific mutation as well as case histories of family members should guide the timing for prophylactic thyroidectomy. Before any surgical procedure, MEN 2 carriers should be screened for pheochromocytoma. There is incomplete penetrance, and about 30% of those with such mutations never manifest endocrine tumors.

Patients may be screened for medullary thyroid carcinoma with a serum calcitonin drawn after 3 days of omeprazole, 20 mg orally twice daily; calcitonin levels rise in the presence of medullary thyroid carcinoma to above 80 pg/mL in women or above 190 pg/mL in men.

MEN 2B

MEN 2B is a familial, autosomal dominant multiglandular syndrome that is caused by a mutation of the *ret* protooncogene (RET) on chromosome 10. MEN 2B is characterized by mucosal neuromas (> 90%) with bumpy and enlarged lips and tongue, Marfan-like habitus (75%), adrenal pheochromocytomas (60%) that are rarely malignant and often bilateral, and medullary thyroid carcinoma (80%). Patients also have intestinal abnormalities (75%) such as intestinal ganglioneuromas, skeletal abnormalities (87%), and delayed puberty (43%).

Medullary thyroid carcinoma is aggressive and presents early in life. Therefore, infants having a parent with MEN 2B receive genetic screening; those carrying the RET mutation undergo a prophylactic total thyroidectomy by age 6 months.

Other Syndromes of Multiple Endocrine Neoplasia

Patients with *Carney complex* develop tumors in the adrenal cortex, pituitary, thyroid, and gonads as well as cardiac myxomas and hyperpigmentation. Patients with *Cowden disease* develop thyroid abnormalities (66%) such as benign adenomas and follicular adenocarcinomas, along with breast cancer (20–36% in women), and multiple hamartomas that affect the skin and multiple other organs. Patients with McCune-Albright syndrome may develop precocious puberty (particularly girls) due to gonadal hypersecretion, Cushing syndrome caused by multiple adrenal nodules, hyperthyroidism from hypersecretory thyroid nodules, and acromegaly caused by GH-secreting pituitary tumors. Patients have fibrous dysplasia of bones and hypophosphatemia, with bone fractures being common. Sudden death has been reported. It is caused by a postzygotic somatic mutatin in the gene coding for the stimulatory G_s protein, resulting in constitutive activation of affected cells.

Clinical Use of Corticosteroids

Mechanisms of Action

Cortisol is a steroid hormone that is normally secreted by the adrenal cortex in response to ACTH. It exerts its action by binding to nuclear receptors which then act upon chromatin to regulate gene expression, producing effects throughout the body.

Relative Potencies

See Table 26–17. Hydrocortisone and cortisone acetate, like cortisol, have mineralocorticoid effects that become excessive at higher doses. Other synthetic corticosteroids such as prednisone, dexamethasone, and deflazacort (an oxazoline derivative of prednisolone) have minimal mineralocorticoid activity. Anticonvulsant drugs (eg, phenytoin, carbamazepine, phenobarbital) accelerate the metabolism of corticosteroids other than hydrocortisone, making them significantly less potent. Megestrol, a synthetic progestin, has slight corticosteroid activity that becomes significant when administered in high doses for appetite stimulation.

Table 26–17. Systemic versus topical activity of corticosteroids.[1]

	Systemic Activity	**Topical Activity**
Prednisone	4–5	1–2
Fluprednisolone	8–10	10
Triamcinolone	5	1
Triamcinolone acetonide	5	40
Dexamethasone	30–120	10
Betamethasone	30	5–10
Betamethasone valerate	—	50–150
Methylprednisolone	5	5
Fluocinolone acetonide	—	40–100
Flurandrenolone acetonide	—	20–50
Fluorometholone	1–2	40

Deflazacart	3–4	—

[1] Hydrocortisone= 1 in potency.

Adverse Effects

Prolonged treatment with systemic corticosteroids causes a variety of adverse effects that can be life-threatening. Patients should be thoroughly informed of the major possible side effects of treatment such as insomnia, personality change, weight gain, muscle weakness, polyuria, kidney stones, diabetes mellitus, sex hormone suppression, occasional amenorrhea in women, candidiasis and opportunistic infections, osteoporosis with fractures, or aseptic necrosis of bones, particularly of the hips, which may become manifest many months after even brief treatment (see section on Cushing syndrome). Patients who receive intermittent high-dose corticosteroids (eg, prednisone 15 mg daily and cumulative dose > 1 g) are at increased risk for osteoporotic fractures. Avascular necrosis of bone develops in about 15% of patients who receive corticosteroids at high doses (eg, prednisone 15 mg daily) for more than 1 month with cumulative prednisone doses of 10 g.

Bisphosphonates (eg, alendronate, 70 mg orally weekly) prevent the development of osteoporosis among patients receiving prolonged courses of corticosteroids. For patients who are unable to tolerate oral bisphosphonates (due to esophagitis, hiatal hernia, or gastritis), periodic intravenous infusions of pamidronate, 60–90 mg, or zoledronic acid, 2–4 mg, should also be effective. Teriparatide, 20 mcg subcutaneously daily for up to 2 years, is also effective against corticosteroid-induced osteoporosis. (See further discussion in Osteoporosis section.) It is wise to follow an organized treatment plan such as the one outlined in in Table 26–18.

Table 26–18. Management of patients receiving systemic corticosteroids.

Recommendations for prescribing

- Do not administer corticosteroids unless absolutely indicated or more conservative measures have failed.
- Keep dosage and duration of administration to the minimum required for adequate treatment.

Monitoring recommendations

- Screen for tuberculosis with a purified protein derivative (PPD) test or chest radiograph before commencing long-term corticosteroid therapy.
- Screen for diabetes mellitus before treatment and at

each physician visit.

—Have patient test urine weekly for glucose.
—Teach patient about the symptoms of hyperglycemia.

- Screen for hypertension before treatment and at each clinician visit.
- Screen for glaucoma and cataracts before treatment, 3 months after treatment inception, and then at least yearly.
- Monitor plasma potassium for hypokalemia and treat as indicated.
- Obtain bone densitometry before treatment and then periodically. Treat osteoporosis.
- Weigh daily. Use dietary measures to avoid obesity and optimize nutrition.
- Measure height frequently to document the degree of axial spine demineralization and compression.
- Watch for fungal or yeast infections of skin, nails, mouth, vagina, and rectum, and treat appropriately.
- With dosage reduction, watch for signs of adrenal insufficiency or corticosteroid withdrawal syndrome.

Patient information

- Prepare the patient and family for possible adverse effects on mood, memory, and cognitive function.
- Inform the patient about other possible side effects,

particularly weight gain, osteoporosis, and aseptic necrosis of bone.
- Counsel to avoid smoking and excessive ethanol consumption.

Prophylactic measures

- Institute a vigorous physical exercise and isometric regimen tailored to each patient's disabilities.
- Administer calcium (1 g elemental calcium) and vitamin D3, 400–800 international units orally daily.

  —Check spot morning urines, and alter dosage to keep urine calcium concentration below 30 mg/dL.
  —If the patient is receiving thiazide diuretics, check for hypercalcemia, and administer only 500 mg elemental calcium daily.
  —Consider a bisphosphonate such as alendronate (70 mg orally weekly) or periodic intravenous infusions of pamidronate or zoledronic acid.

- Avoid prolonged bed rest that will accelerate muscle weakness and bone mineral loss. Ambulate early after fractures.
- Avoid elective surgery, if possible. Vitamin A in a daily dose of 20,000 units orally for 1 week may improve wound healing, but it is not prescribed in pregnancy.
- Avoid activities that could cause falls or other

trauma.

- For ulcer prophylaxis, if administering corticosteroids with nonsteroidals, prescribe a proton pump inhibitor (not required for corticosteroids alone). Avoid large doses of antacids containing aluminum hydroxide (many popular brands) because aluminum hydroxide binds phosphate and may cause a hypophosphatemic osteomalacia that can compound corticosteroid osteoporosis.
- Treat hypogonadism.
- Treat infections aggressively. Consider unusual pathogens.
- Treat edema as indicated.

Diabetes Mellitus

Essentials of Diagnosis

Type 1 diabetes:

- Polyuria, polydipsia, and weight loss associated with random plasma glucose 200 mg/dL.
- Plasma glucose of 126 mg/dL or higher after an overnight fast, documented on more than one occasion.
- Ketonemia, ketonuria, or both.
- Islet autoantibodies are frequently present.

Type 2 diabetes:

- Most patients are over 40 years of age and obese.
- Polyuria and polydipsia. Ketonuria and weight loss generally are uncommon at time of diagnosis. Candidal vaginitis in women may be an initial manifestation. Many patients have few or no symptoms.
- Plasma glucose of 126 mg/dL or higher after an overnight fast on more than one occasion. After 75 g oral glucose, diagnostic values are 200 mg/dL or more 2 hours after the oral glucose.
- Hypertension, dyslipidemia, and atherosclerosis are often associated.

Epidemiologic Considerations

In 2007, an estimated 23.6 million people in the United States had diabetes mellitus, of which approximately 1 million have type 1 diabetes and the rest mostly have type 2 diabetes. A third group that was designated as "other specific types" by the American Diabetes Association (ADA) (Table 27–1) number only in the thousands. Among these are the rare monogenic defects of either B cell function or of insulin action, primary diseases of the exocrine pancreas, endocrinopathies, and drug-induced diabetes. Updated information about the prevalence of diabetes in the United States is available from the Centers for Disease Control and Prevention (http://www.cdc.gov/diabetes/pubs/estimates.htm#prev).

Table 27–1. Other specific types of diabetes mellitus.
Genetic defects of pancreatic B cell function
MODY 1 (HNF-4); rare
MODY 2 (glucokinase); less rare
MODY 3 (HNF-1); accounts for two-thirds of all MODY
MODY 4 (IPF-1); very rare
MODY 5 (HNF-1); very rare
MODY 6 (neuroD1); very rare
Mitochondrial DNA

Genetic defects in insulin action
Type A insulin resistance
Leprechaunism
Rabson-Mendenhall syndrome
Lipoatrophic diabetes
Diseases of the exocrine pancreas
Endocrinopathies
Drug- or chemical-induced diabetes
Other genetic syndromes (Down, Klinefelter, Turner, others) sometimes associated with diabetes

MODY, maturity-onset diabetes of the young.

Classification & Pathogenesis

Diabetes mellitus is a syndrome with disordered metabolism and inappropriate hyperglycemia due to either a deficiency of insulin secretion or to a combination of insulin resistance and inadequate insulin secretion to compensate. Type 1 diabetes is due to pancreatic islet B cell destruction predominantly by an autoimmune process, and these patients are prone to ketoacidosis. Type 2 diabetes is the more prevalent form and results from insulin resistance with a defect in compensatory insulin secretion (Table 27–2).

Table 27–2. Clinical classification of common diabetes mellitus syndromes.

Type	**Ketosis**	**Islet Cell Antibodies**	**HLA Association**	**Treatment**
Type 1				
(A) Immune-mediated	Present	Present at onset	Positive	Eucaloric healthy diet and preprandial rapidly acting insulin, plus basal insulin replacement with intermediate-acting or long-acting insulin
(B) Idiopathic	Present	Absent	Absent	
Type 2				
(A) Nonobese	Absent	Absent	Negative	(1) Eucaloric diet alone (2) Diet plus insulin or oral agents

(B) Obese	Absent	Absent	Negative	(1) Weight reduction (2) Hypocaloric diet, plus oral agents or insulin

Type 1 Diabetes Mellitus

This form of diabetes is immune-mediated in over 90% of cases and idiopathic in less than 10%. The rate of pancreatic B cell destruction is quite variable, being rapid in some individuals and slow in others. Type 1 diabetes is usually associated with ketosis in its untreated state. It occurs at any age but most commonly arises in children and young adults with a peak incidence before school age and again at around puberty. It is a catabolic disorder in which circulating insulin is virtually absent, plasma glucagon is elevated, and the pancreatic B cells fail to respond to all insulinogenic stimuli. Exogenous insulin is therefore required to reverse the catabolic state, prevent ketosis, reduce the hyperglucagonemia, and reduce blood glucose.

Immune-mediated type 1 diabetes mellitus (type 1A)

The highest incidence of immune-mediated type 1 diabetes mellitus is in Scandinavia and northern Europe, where the annual incidence is as high as 37 per 100,000 children aged 14 years or younger in Finland, 27 per 100,000 in Sweden, 22 per 100,000 in Norway, and 19 per 100,000 in the United Kingdom. The annual incidence of type 1 diabetes decreases across the rest of Europe to 10 per 100,000 in Greece and 8 per 100,000 in France. Surprisingly, the island of Sardinia has as high an annual incidence as Finland (37 per 100,000) even though in the rest of Italy, including the island of Sicily, it is only 10 per 100,000 per year. In the United States, the annual incidence of type 1 diabetes averages 15 per 100,000, with higher rates in states more densely populated with persons of Scandinavian descent such as Minnesota. Worldwide, the lowest incidence of type 1 diabetes (< 1 case per 100,000 per year) is in China and parts of South America. The global incidence of type 1 diabetes is increasing (approximately 3% each year).

Approximately one-third of the disease susceptibility is due to genes and two-thirds to environmental factors. Genes that are related to the HLA locus contribute about 40% of the genetic risk. About 95% of patients with type 1 diabetes possess either HLA-DR3 or HLA-DR4, compared with 45–50% of white controls. *HLA-DQ* genes are even more specific markers of type 1 susceptibility, since a particular variety *(HLA-DQB1*0302)* is found in the DR4 patients with type 1, while a "protective" gene *(HLA-DQB1*0602)* is often present in the DR4 controls.

The other important gene that contributes to about 10% of the genetic risk is found at the 5' polymorphic region of the insulin gene. This polymorphic region affects the expression of the insulin gene in the thymus and results in depletion of insulin-specific T lymphocytes. In linkage studies, 16 other genetic regions of the human genome have been identified as being important to pathogenesis but less is known about them.

Most patients with type 1 diabetes mellitus have circulating antibodies to islet cells (ICA), insulin (IAA), glutamic acid decarboxylase (GAD65), and tyrosine phosphatases (IA-2 and IA2-) at the time the diagnosis is made. These antibodies facilitate screening for an autoimmune cause of diabetes, particularly screening siblings of affected children, as well as adults with atypical features of type 2 diabetes (Table 27–3). An additional autoantibody to a zinc transporter ZnT8 (Slc30A8) was recently found to be present in about 28% of type 1 diabetes patients who were negative for the other antibodies. Screening with zinc transporter, GAD65, IA2 and IAA autoantibodies may identify about 98% of people who have an autoimmune basis for their beta cell loss. Antibody levels decline with increasing duration of disease. Also, low levels of anti-insulin antibodies develop in almost all patients once they are treated with insulin.

Table 27–3. Diagnostic sensitivity and specificity of autoimmune markers in patients with newly diagnosed type 1 diabetes mellitus.

	Sensitivity	**Specificity**
Glutamic acid decarboxylase (GAD65)	70–90%	99%
Insulin (IAA)	40–70%	99%
Tyrosine phosphatase (IA-2)	50–70%	99%

Family members of diabetic probands are at increased lifetime risk for developing type 1 diabetes. A child whose mother has type 1 diabetes has a 3% risk of developing the disease and a 6% risk if the child's father has it. The risk in siblings is related to the number of HLA haplotypes that the sibling shares with the diabetic proband. If one haplotype is shared, the risk is 6% and if two haplotypes are shared, the risk increases to 12–25%. The highest risk is for identical twins, where the concordance rate is 25–50%.

Some patients with a milder expression of type 1 diabetes mellitus initially retain enough B cell function to avoid ketosis, but as their B cell mass diminishes later in life, dependence on insulin therapy develops. Islet cell antibody surveys among northern Europeans indicate that up to 15% of "type 2" diabetic patients may actually have this mild form of type 1 diabetes (latent autoimmune diabetes of adulthood; LADA). Evidence for environmental factors playing a role in the development of type 1 diabetes include the observation that the disease is more common in Scandinavian countries and becomes progressively less frequent in countries nearer and nearer to the equator. Also, the risk for type 1 diabetes increases when individuals who normally have a low risk emigrate to the Northern Hemisphere. For example, it was recently shown that Pakistani children born and raised in Bradford, England have a higher risk for developing type 1 diabetes compared with children who lived in Pakistan all their lives.

Which environmental factor is responsible for the increased risk is not known. There have been a number of different hypotheses including infections with certain viruses (rubella, Coxsackie B4) and consumption of cow's milk. Also, in developed countries, childhood infections have become less frequent and so perhaps the immune system becomes dysregulated with development of autoimmunity and conditions such as asthma and diabetes. This theory is referred to as the hygiene hypothesis. None of these factors has so far been confirmed as the culprit. Part of the difficulty is that autoimmune injury undoubtedly starts many years before clinical diabetes mellitus develops.

Idiopathic type 1 diabetes mellitus (type 1B)

Less than 10% of subjects have no evidence of pancreatic B cell autoimmunity to explain their insulinopenia and ketoacidosis. This subgroup has been classified as "idiopathic type 1 diabetes" and designated as "type 1B." Although only a minority of patients with type 1 diabetes fall into this group, most of these are of Asian or African origin. It was recently reported that about 4% of the West Africans with ketosis-prone diabetes are homozygous for a mutation in *PAX-4 (Arg133Trp)*—a gene that is essential for the development of pancreatic islets.

Type 2 Diabetes Mellitus

This represents a heterogeneous group of conditions that used to occur predominantly in adults, but it is now more frequently encountered in children and adolescents. More than 90% of all diabetic persons in the United States are included under this classification. Circulating endogenous insulin is sufficient to prevent ketoacidosis but is inadequate to prevent hyperglycemia in the face of increased needs owing to tissue insensitivity (insulin resistance).

See Related Guideline from *CURRENT Practice Guidelines in Primary Care 2009*

Genetic and environmental factors combine to cause both the insulin resistance and the beta cell loss. Most epidemiologic data indicate strong genetic influences, since in monozygotic twins over 40 years of age, concordance develops in over 70% of cases within a year whenever type 2 diabetes develops in one twin. Genome-wide association studies have made considerable progress in identifying the at-risk genes. So far, 18 different genetic loci have been associated with an increased risk of type 2 diabetes. A significant number of the identified loci appear to code for proteins that have a role in beta cell function or development. One of the genetic loci with the largest risk effect is *TCF7L2*. This gene codes for a transcription factor involved in the WNT signaling pathway that is required for normal pancreatic development. Alleles at other genetic loci (*CDKAL1, SLC30A8, HHEX-IDE, CDKN2A/B, KCNJ11,* and *IGF2BP2)* are thought to affect insulin secretion. Two loci (*FTO* and *MC4R*) affect fat mass and obesity risk. The *PPARG* locus has been implicated in insulin resistance. The loci identified to date still explain only some of the heritable risk for diabetes; clearly, other loci remain to be discovered.

Early in the disease process, hyperplasia of pancreatic B cells occurs and probably accounts for the fasting hyperinsulinism and exaggerated insulin and proinsulin responses to glucose and other stimuli. With time, chronic deposition of amyloid in the islets may combine with inherited genetic defects progressively to impair B cell function.

Obesity is the most important environmental factor causing insulin resistance. The degree and prevalence of obesity varies among different racial groups with type 2 diabetes. While obesity is apparent in no more than 30% of Chinese and Japanese patients with type 2, it is found in 60–70% of North Americans, Europeans, or Africans with type 2 and approaches 100% of patients with type 2 among Pima Indians or Pacific Islanders from Nauru or Samoa.

Visceral obesity, due to accumulation of fat in the omental and mesenteric regions, correlates with insulin resistance; subcutaneous abdominal fat seems to have less of an association with insulin insensitivity. There are many patients with type 2 diabetes who, while not overtly obese, have increased visceral fat; they are termed the "metabolically obese." Exercise may affect the deposition of visceral fat as suggested by CT scans of Japanese wrestlers, whose extreme obesity is predominantly subcutaneous. Their daily vigorous exercise program prevents accumulation of visceral fat, and they have normal serum lipids and euglycemia despite daily intakes of 5000–7000 kcal and development of massive subcutaneous obesity. Several **adipokines**, secreted by fat cells, can affect insulin action in obesity. Two of these, **leptin** and **adiponectin**, seem to increase sensitivity to insulin, presumably by increasing hepatic responsiveness.

Two others—**tumor necrosisfactor-** , which inactivates insulin receptors, and **resistin,** which interferes with insulin action on glucose glucose metabolism—have been reported to be elevated in obese animal models. Abnormal levels of these adipokines may contribute to the development of insulin resistance in human obesity.

Hyperglycemia per se can impair insulin action by causing accumulation of hexosamines in muscle and fat tissue and by inhibiting glucose transport (acquired glucose toxicity). Correction of hyperglycemia reverses this acquired insulin resistance.

Other Specific Types of Diabetes Mellitus

Maturity-onset diabetes of the young (MODY)

This subgroup is a relatively rare monogenic disorder characterized by non–insulin-dependent diabetes with autosomal dominant inheritance and an age at onset of 25 years or younger. Patients are nonobese, and their hyperglycemia is due to impaired glucose-induced secretion of insulin. Six types of MODY have been described. Except for MODY 2, in which a glucokinase gene is defective, all other types involve mutations of a nuclear transcription factor that regulates islet gene expression.

MODY 2 is quite mild, associated with only slight fasting hyperglycemia and few if any microvascular diabetic complications. It generally responds well to hygienic measures or low doses of oral hypoglycemic agents. MODY 3—the most common form—accounts for two-thirds of all MODY cases. The clinical course is similar to that of idiopathic type 2 diabetes in terms of microangiopathy and failure to respond to oral agents with time.

Diabetes due to mutant insulins

This is a very rare subtype of nonobese type 2 diabetes, with no more than ten families having been described. Since affected individuals were heterozygous and possessed one normal insulin gene, diabetes was mild, did not appear until middle age, and showed autosomal dominant genetic transmission. There is generally no evidence of clinical insulin resistance, and these patients respond well to standard therapy.

Diabetes due to mutant insulin receptors

Defects in one of their insulin receptor genes have been found in more than 40 people with diabetes, and most have extreme insulin resistance associated with acanthosis nigricans (Plate 91). In very rare instances when both insulin receptor genes are abnormal, newborns present with a leprechaun-like phenotype and seldom live through infancy.

Plate 91

Acanthosis nigricans on the neck of a patient with type 2 diabetes mellitus (courtesy of Richard P. Usatine, MD; Used, with permission, from Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H, Tysinger J. *The Color Atlas of Family Medicine*. McGraw-Hill, 2009.)

Diabetes mellitus associated with a mutation of mitochondrial DNA

Since sperm do not contain mitochondria, only the mother transmits mitochondrial genes to her offspring. Diabetes due to mutations of mitochondrial DNA occurs in less than 2% of patients with diabetes. The most common cause is the A3243G mutation in the gene coding for the tRNA (Leu,UUR). Diabetes occurs even when a small percentage of the mitochondria in the cell carry the mutation; the heteroplasmy levels in the leukocytes range from 1% to 40%. Diabetes usually develops in these patients in their late 30s, and characteristically, they also have hearing loss (maternally inherited diabetes and deafness [MIDD]). In some patients, the beta cell failure can be rapidly progressive and patients require insulin soon after diagnosis. Other patients can be managed by diet or oral agents for a while but most eventually require insulin. MIDD patients are not usually overweight; they resemble patients with type 1 diabetes mellitus but without evidence for autoimmunity.

Wolfram syndrome

Wolfram syndrome is an autosomal recessive neurodegenerative disorder first evident in childhood. It consists of diabetes insipidus, diabetes mellitus, optic atrophy, and deafness, hence the acronym DIDMOAD. It is due to mutations in a gene named *WFS1*, which encodes a 100.3 KDa transmembrane protein localized in the endoplasmic reticulum. Diabetes develops in mice with mutated form of this protein; and isolated islets from these mice show impairment in insulin secretion to glucose stimulus and increased apoptosis. The diabetes mellitus usually presents in the first decade together with the optic atrophy. Cranial diabetes insipidus and sensorineural deafness develop during the second decade in 60–75% of patients. Ureterohydronephrosis, neurogenic bladder, cerebellar ataxia, peripheral neuropathy, and psychiatric illness develop later in many patients.

Insulin Resistance Syndrome (Syndrome X; Metabolic Syndrome)

Twenty-five percent of the general nonobese nondiabetic population has insulin resistance of a magnitude similar to that seen in type 2 diabetes. These insulin-resistant nondiabetic individuals are at much higher risk for developing type 2 diabetes than insulin-sensitive persons. In addition to diabetes, these individuals have increased risk for elevated plasma triglycerides, lower high-density lipoproteins (HDLs), and higher blood pressure—a cluster of abnormalities termed syndrome X. These associations have now been expanded to include small, dense, low-density lipoprotein (LDL), hyperuricemia, abdominal obesity, prothrombotic state with increased levels of plasminogen activator inhibitor type 1 (PAI-1), and proinflammatory state. These clusters of abnormalities significantly increase the risk of atherosclerotic disease.

It has been postulated that hyperinsulinemia and insulin resistance play a direct role in these metabolic abnormalities, but supportive evidence is inconclusive. Although hyperinsulinism and hypertension often coexist in whites, that is not the case in blacks or Pima Indians. Moreover, patients with hyperinsulinism due to insulinoma are not hypertensive, and there is no fall in blood pressure after surgical removal of the insulinoma restores normal insulin levels. The main value of grouping these disorders as a syndrome, however, is to remind clinicians that the therapeutic goals are not only to correct hyperglycemia but also to manage the elevated blood pressure and dyslipidemia that result in increased cerebrovascular and cardiac morbidity and mortality in these patients.

Clinical Findings

The principal clinical features of the two major types of diabetes mellitus are listed for comparison in Table 27–4.

Table 27–4. Clinical features of diabetes at diagnosis.

	Type 1 Diabetes	**Type 2 Diabetes**
Polyuria and thirst	++	+
Weakness or fatigue	++	+
Polyphagia with weight loss	++	–
Recurrent blurred vision	+	++
Vulvovaginitis or pruritus	+	++
Peripheral neuropathy	+	++
Nocturnal enuresis	++	–
Often asymptomatic	–	++

Patients with type 1 diabetes have a characteristic symptom complex. An absolute deficiency of insulin results in accumulation of circulating glucose and fatty acids, with consequent hyperosmolality and hyperketonemia.

Patients with type 2 diabetes may or may not have characteristic features. The presence of obesity or a strongly positive family history for mild diabetes suggests a high risk for the development of type 2 diabetes.

Symptoms and Signs

Type 1 diabetes

Increased urination is a consequence of osmotic diuresis secondary to sustained hyperglycemia. This results in a loss of glucose as well as free water and electrolytes in the urine. Thirst is a consequence of the hyperosmolar state, as is blurred vision, which often develops as the lenses are exposed to hyperosmolar fluids.

Weight loss despite normal or increased appetite is a common feature of type 1 when it develops subacutely. The weight loss is initially due to depletion of water, glycogen, and triglycerides; thereafter, reduced muscle mass occurs as amino acids are diverted to form glucose and ketone bodies.

Lowered plasma volume produces symptoms of postural hypotension. Total body potassium loss and the general catabolism of muscle protein contribute to the weakness.

Paresthesias may be present at the time of diagnosis, particularly when the onset is subacute. They reflect a temporary dysfunction of peripheral sensory nerves, which clears as insulin replacement restores glycemic levels closer to normal, suggesting neurotoxicity from sustained hyperglycemia.

When absolute insulin deficiency is of acute onset, the above symptoms develop abruptly. Ketoacidosis exacerbates the dehydration and hyperosmolality by producing anorexia and nausea and vomiting, interfering with oral fluid replacement.

The patient's level of consciousness can vary depending on the degree of hyperosmolality. When insulin deficiency develops relatively slowly and sufficient water intake is maintained, patients remain relatively alert and physical findings may be minimal. When vomiting occurs in response to worsening ketoacidosis, dehydration progresses and compensatory mechanisms become inadequate to keep serum osmolality below 320–330 mosm/L. Under these circumstances, stupor or even coma may occur. The fruity breath odor of acetone further suggests the diagnosis of diabetic ketoacidosis.

Hypotension in the recumbent position is a serious prognostic sign. Loss of subcutaneous fat and muscle wasting are features of more slowly developing insulin deficiency. In occasional patients with slow, insidious onset of insulin deficiency, subcutaneous fat may be considerably depleted.

Type 2 diabetes

While many patients with type 2 diabetes present with increased urination and thirst, many others have an insidious onset of hyperglycemia and are asymptomatic initially. This is particularly true in obese patients, whose diabetes may be detected only after glycosuria or hyperglycemia is noted during routine laboratory studies. Occasionally, type 2 patients may present with evidence of neuropathic or cardiovascular complications because of occult disease present for some time prior to diagnosis. Chronic skin infections are common. Generalized pruritus and symptoms of vaginitis are frequently the initial complaints of women. Diabetes should be suspected in women with chronic candidal vulvovaginitis as well as in those who have delivered large babies (> 9 lb, or 4.1 kg) or have had polyhydramnios, preeclampsia, or unexplained fetal losses.

Obese diabetics may have any variety of fat distribution; however, diabetes seems to be more often associated in both men and women with localization of fat deposits on the upper segment of the body (particularly the abdomen, chest, neck, and face) and relatively less fat on the appendages, which may be quite muscular. Standardized tables of waist-to-hip ratio indicate that ratios of "greater than 0.9" in men and "greater than 0.8" in women are associated with an increased risk of diabetes in obese subjects. Mild hypertension is often present in obese diabetics. Eruptive xanthomas on the flexor surface of the limbs and on the buttocks and lipemia retinalis due to hyperchylomicronemia can occur in patients with uncontrolled type 2 diabetes who also have a familial form of hypertriglyceridemia.

Laboratory Findings

Urinalysis

Glucosuria

A specific and convenient method to detect glucosuria is the paper strip impregnated with glucose oxidase and a chromogen system (Clinistix, Diastix), which is sensitive to as little as 0.1% glucose in urine. Diastix can be directly applied to the urinary stream, and differing color responses of the indicator strip reflect glucose concentration.

A normal renal threshold for glucose as well as reliable bladder emptying is essential for interpretation.

Ketonuria

Qualitative detection of ketone bodies can be accomplished by nitroprusside tests (Acetest or Ketostix).

Although these tests do not detect -hydroxybutyric acid, which lacks a ketone group, the semiquantitative estimation of ketonuria thus obtained is nonetheless usually adequate for clinical purposes. Many laboratories now measure -hydroxybutyric acid, and there is now a meter available (Precision Xtra, Abbott Diabetes Care) for patient use that measures -hydroxybutyric acid levels in capillary glucose samples.

Blood testing procedures

Glucose tolerance test

Methodology and normal fasting glucose

Plasma or serum from venous blood samples has the advantage over whole blood of providing values for glucose that are independent of hematocrit and that reflect the glucose concentration to which body tissues are exposed. For these reasons, and because plasma and serum are more readily measured on automated equipment, they are used in most laboratories. If serum is used or if plasma is collected from tubes that lack an agent to block glucose metabolism (such as fluoride), samples should be refrigerated and separated within 1 hour after collection. The glucose concentration is 10–15% higher in plasma or serum than in whole blood because structural components of blood cells are absent.

Criteria for laboratory confirmation of diabetes mellitus

If the fasting plasma glucose level is 126 mg/dL or higher on more than one occasion, further evaluation of the patient with a glucose challenge is unnecessary. However, when fasting plasma glucose is less than 126 mg/dL in suspected cases, a standardized oral glucose tolerance test may be done (Table 27–5).

Table 27–5. The Diabetes Expert Committee criteria for evaluating the standard oral glucose tolerance test.[1]

	Normal Glucose Tolerance	**Impaired Glucose Tolerance**	**Diabetes Mellitus**[2]
Fasting plasma glucose (mg/dL)	< 110	110–125	126
Two hours after glucose load (mg/dL)	< 140	140–199	200

---

[1] Give 75 g of glucose dissolved in 300 mL of water after an overnight fast in persons who have been receiving at least 150–200 g of carbohydrate daily for 3 days before

the test.

[2] A fasting plasma glucose 126 mg/dL is diagnostic of diabetes if confirmed on a subsequent day.

For proper evaluation of the test, the subjects should be normally active and free from acute illness. Medications that may impair glucose tolerance include diuretics, contraceptive drugs, glucocorticoids, niacin, and phenytoin.

Because of difficulties in interpreting oral glucose tolerance tests and the lack of standards related to aging, these tests are being replaced by documentation of fasting hyperglycemia.

Glycated hemoglobin (hemoglobin A_1) measurements

Hemoglobin becomes glycated by ketoamine reactions between glucose and other sugars and the free amino groups on the and chains. Only glycation of the N-terminal valine of the beta chain imparts sufficient negative charge to the hemoglobin molecule to allow separation by charge dependent techniques. These charge separated hemoglobins are collectively referred to as hemoglobin A_1 (HbA_1). The major form of HbA_1 is hemoglobin A_{1c} (HbA_{1c}) where glucose is the carbohydrate. HbA_{1c} comprises 4–6% of total hemoglobin A_1. The remaining HbA_1 species contain fructose-1,6 diphosphate (HbA$_{1a1}$); glucose-6-phosphate (HbA$_{1a2}$); and unknown carbohydrate moiety (HbA$_{1b}$). The hemoglobin A$_{1c}$ fraction is abnormally elevated in diabetic persons with chronic hyperglycemia. Methods for measuring HbA$_{1c}$ include electrophoresis, cation-exchange chromatography, boronate affinity chromatography, and immunoassays. Office-based immunoassays using capillary blood give a result in about 9 minutes and this allows for immediate feedback to the patients regarding their glycemic control.

Since glycohemoglobins circulate within red blood cells whose life span lasts up to 120 days, they generally reflect the state of glycemia over the preceding 8–12 weeks, thereby providing an improved method of assessing diabetic control. The HbA$_{1c}$ value, however, is weighted to more recent glucose levels (previous month) and this explains why significant changes in HbA$_{1c}$ are observed with short-term (1 month) changes in mean plasma glucose levels. Measurements should be made in patients with either type of diabetes mellitus at 3- to 4-month intervals so that adjustments in therapy can be made if HbA$_{1c}$ is either subnormal or if it is more than 2% above the upper limits of normal for a particular laboratory. In patients monitoring their own blood glucose levels, HbA$_{1c}$ values provide a valuable check on the accuracy of monitoring. In patients who do not monitor their own blood glucose levels, HbA$_{1c}$ values are essential for adjusting therapy. There is a linear relationship between the HbA$_{1c}$ and the average glucose levels in the previous 3 months as determined from continuous glucose monitoring data and from seven-point capillary blood glucose profiles (preprandial, postprandial, and bedtime). Table 27–6 gives the mean capillary glucose values for HbA$_{1c}$ values ranging from 5% to 12%. Use of HbA$_{1c}$ for screening is controversial. Sensitivity in detecting known diabetes cases by HbA$_{1c}$ measurements is only 85%, indicating that diabetes cannot be excluded by a normal value. On the other hand, elevated HbA$_{1c}$ assays are fairly specific (91%) in identifying the presence of diabetes.

Table 27–6. Correlations of HbA$_{1c}$ levels with average of capillary glucose measurements (preprandial, postprandial and bedtime) in the previous 3 months.

HbA$_{1c}$ value (%) determined using DCCT aligned assays	**Mean capillary blood glucose levels (mg/dL)**
5	97
6	126
7	154
8	183
9	212
10	240

11	269
12	298

Adapted, with permission, from Nathan et al. Translating the A_{1C} assay into estimated average glucose values. Diabetes Care 2008 Aug;31(8): 1473–8.

The accuracy of HbA_{1c} values can be affected by hemoglobin variants or derivatives; the effect depends on the specific hemoglobin variant or derivative and the specific assay used. Immunoassays that use an antibody to the glycated amino terminus of globin do not recognize the terminus of the globin of hemoglobin F. Thus, in patients with high levels of hemoglobin F, immunoassays give falsely low values of HbA_{1c}. Cation-exchange chromatography separates hemoglobin species by charge differences. Hemoglobin variants that co-elute with HbA_{1c} can lead to an overestimation of the HbA_{1c} value. Chemically modified derivatives of hemoglobin such as carbamoylation (in end-stage chronic kidney disease) or acetylation (high-dose aspirin therapy) can similarly co-elute with HbA_{1c} by some assay methods.

Any condition that shortens erythrocyte survival or decreases mean erythrocyte age (eg, recovery from acute blood loss, hemolytic anemia) will falsely lower HbA_{1c} irrespective of the assay method used. Alternative methods such as fructosamine (see below) should be considered for these patients. Vitamins C and E are reported to falsely lower test results possibly by inhibiting glycation of hemoglobin.

Serum fructosamine

Serum fructosamine is formed by nonenzymatic glycosylation of serum proteins (predominantly albumin). Since serum albumin has a much shorter half-life than hemoglobin, serum fructosamine generally reflects the state of glycemic control for only the preceding 1–2 weeks. Reductions in serum albumin (eg, nephrotic state or hepatic disease) will lower the serum fructosamine value. When abnormal hemoglobins or hemolytic states affect the interpretation of glycohemoglobin or when a narrower time frame is required, such as for ascertaining glycemic control at the time of conception in a diabetic woman who has recently become pregnant, serum fructosamine assays offer some advantage. Normal values vary in relation to the serum albumin concentration and are 1.5–2.4 mmol/L when the serum albumin level is 5 g/dL.

Self-monitoring of blood glucose

Capillary blood glucose measurements performed by patients themselves, as outpatients, are extremely useful. In type 1 patients in whom "tight" metabolic control is attempted, they are indispensable. There are several paper strip (glucose oxidase, glucose dehydrogenase, or hexokinase) methods for measuring glucose on capillary blood samples. A reflectance photometer or an amperometric system is then used to measure the reaction that takes place on the reagent strip. A large number of blood glucose meters are now available. All are accurate, but they vary with regard to speed, convenience, size of blood samples required, and cost. Popular models include those manufactured by LifeScan (One Touch), Bayer Corporation (Ascencia), Roche Diagnostics (Accu-Chek), Abbott Laboratories (Precision, FreeStyle), and Home Diagnostics (Prestige). These blood glucose meters are relatively inexpensive, ranging from $50 to $100 each. Test strips remain a major expense, costing $.50 to $.75 apiece. Each glucose meter comes with a lancet device and disposable 26- to 33-gauge lancets. For some meters, there is a code associated with every batch of test strips, and this code needs to be entered into the meter before the strips can be used. Failure to properly code the meter can result in inaccurate readings. Patients not infrequently forget to change the code and it is preferable to give patients meters that do not require coding. The accuracy of data obtained by home glucose monitoring does require education of the patient in sampling and measuring procedures as well as in properly calibrating the instruments.

The clinician should be aware of the limitations of the self-monitoring glucose systems. First, a few of the older meters (such as the One Touch Profile) are calibrated against whole blood glucose concentrations even though the test strip measures the glucose in the plasma fraction. This means the displayed values are 10% to 15% *lower* than the laboratory glucose result. Second, increases or decreases in hematocrit can decrease or increase the measured glucose values. The mechanism underlying this effect is not known but presumably it is due to the impact of red cells on the diffusion of plasma into the reagent layer. Third, the meters and the test strips are calibrated over the glucose concentrations ranging from 60 mg/dL to 160 mg/dL, and the accuracy is not as good for higher and lower glucose levels. When the glucose is less than 60 mg/dL, the difference between the meter and the laboratory value may be as much as 20%. Fourth, glucose oxidase–based amperometric systems underestimate glucose levels in the presence of high oxygen tension. This may be important in the critically ill who are receiving supplemental oxygen; under these circumstances, a glucose dehydrogenase–based system may be preferable. Fifth, some meters have been approved for measuring glucose in blood samples obtained at alternative sites such as the forearm and thigh. There is, however, a 5- to 20-minute lag in the glucose response on the arm with respect to the glucose response on the finger. Forearm blood glucose measurements could therefore result in a delay in detection of rapidly developing hypoglycemia.

Continuous glucose monitoring systems

Three continuous glucose monitoring systems are currently available for clinical use. The MiniMed Medtronic, Navigator, and DexCom systems involve inserting a subcutaneous sensor (rather like an insulin pump cannula) that measures glucose concentrations in the interstitial fluid for 3, 5, or 7 days, respectively. The data are transmitted to a separate pager-like device with a screen. The MiniMed system also has the option to wirelessly transmit the data to the screen of their insulin pump. The systems allow the patient to set "alerts" for low and high glucose values and rate of change of glucose levels. Patients still have to calibrate the devices with periodic fingerstick glucose levels, and since there are concerns regarding reliability, it is still necessary to confirm the displayed glucose level with a fingerstick glucose before making interventions such as injecting extra insulin or eating extra carbohydrates. A 6-month randomized controlled study of type 1 patients showed that adults (25 years and older) using these systems had improved glycemic control without an increase in the incidence of hypoglycemia. A randomized controlled study of continuous glucose monitoring during pregnancy showed improved glycemic control in the third trimester, lower birth weight, and reduced risk of macrosomia. The individual glucose values are not that critical—what matters is the direction and the rate at which the glucose is changing, allowing the user to take corrective action. The wearer also gains insight into the way particular foods and activities affect their glucose levels. The other main benefit is the low glucose alert warning. These systems are not covered by insurance and the initial cost is about $800 to $1000, and the sensor, which has to be changed every 3 to 7 days, costs $35 to $60. This adds up to an out-of-pocket expense of about $4000 annually.

Lipoprotein abnormalities in diabetes

Circulating lipoproteins are just as dependent on insulin as is the plasma glucose. In type 1 diabetes, moderately deficient control of hyperglycemia is associated with only a slight elevation of LDL cholesterol and serum triglycerides and little if any change in HDL cholesterol. Once the hyperglycemia is corrected, lipoprotein levels are generally normal. However, in patients with type 2 diabetes, a distinct "diabetic dyslipidemia" is characteristic of the insulin resistance syndrome. Its features are a high serum triglyceride level (300–400 mg/dL), a low HDL cholesterol (less than 30 mg/dL), and a qualitative change in LDL particles, producing a smaller dense particle whose membrane carries supranormal amounts of free cholesterol. These smaller dense LDL particles are more susceptible to oxidation, which renders them more atherogenic. Since a low HDL cholesterol is a major feature predisposing to macrovascular disease, the term "dyslipidemia" has preempted the term "hyperlipidemia," which mainly denoted the elevated triglycerides. Measures designed to correct the obesity and hyperglycemia, such as exercise, diet, and hypoglycemic therapy, are the treatment of choice for diabetic dyslipidemia, and in occasional patients in whom normal weight was achieved, all features of the lipoprotein abnormalities cleared. Since primary disorders of lipid metabolism may coexist with diabetes, persistence of lipid abnormalities after restoration of normal weight and blood glucose should prompt a diagnostic workup and possible pharmacotherapy of the lipid disorder. Chapter 28: Lipid Disorders discusses these matters in detail.

Differential Diagnosis

Hyperglycemia Secondary to Other Causes

Secondary hyperglycemia has been associated with various disorders of insulin target tissues (liver, muscle, and adipose tissue) (Table 27–7). Other secondary causes of carbohydrate intolerance include endocrine disorders—often specific endocrine tumors—associated with excess production of growth hormone, glucocorticoids, catecholamines, glucagon, or somatostatin. In the first four situations, peripheral responsiveness to insulin is impaired. With excess of glucocorticoids, catecholamines, or glucagon, increased hepatic output of glucose is a contributory factor; in the case of catecholamines, decreased insulin release is an additional factor in producing carbohydrate intolerance, and with excess somatostatin production it is the major factor.

Table 27–7. Secondary causes of hyperglycemia.
Hyperglycemia due to tissue insensitivity to insulin
Hormonal tumors (acromegaly, Cushing syndrome, glucagonoma, pheochromocytoma)
Pharmacologic agents (corticosteroids, sympathomimetic drugs, niacin)
Liver disease (cirrhosis, hemochromatosis)
Muscle disorders (myotonic dystrophy)
Adipose tissue disorders (lipodystrophy, truncal obesity)
Insulin receptor disorders (acanthosis nigricans syndromes, leprechaunism)
Hyperglycemia due to reduced insulin secretion
Hormonal tumors (somatostatinoma, pheochromocytoma)
Pancreatic disorders (pancreatitis, hemosiderosis, hemochromatosis)

Pharmacologic agents (thiazide diuretics, phenytoin, pentamidine)

A rare syndrome of extreme insulin resistance associated with acanthosis nigricans afflicts either young women with androgenic features as well as insulin receptor mutations or older people, mostly women, in whom a circulating immunoglobulin binds to insulin receptors and reduces their affinity to insulin.

Medications such as diuretics, phenytoin, niacin, and high-dose corticosteroids can produce hyperglycemia that is reversible once the drugs are discontinued or when diuretic-induced hypokalemia is corrected. Chronic pancreatitis or subtotal pancreatectomy reduces the number of functioning B cells and can result in a metabolic derangement very similar to that of genetic type 1 diabetes except that a concomitant reduction in pancreatic A cells may reduce glucagon secretion so that relatively lower doses of insulin replacement are needed. Insulin-dependent diabetes is occasionally associated with Addison disease and autoimmune thyroiditis (**Schmidt syndrome**, or **polyglandular failure syndrome**). This occurs more commonly in women and represents an autoimmune disorder in which there are circulating antibodies to adrenocortical and thyroid tissue, thyroglobulin, and gastric parietal cells.

Nondiabetic Glycosuria

Nondiabetic glycosuria (renal glycosuria) is a benign asymptomatic condition wherein glucose appears in the urine despite a normal amount of glucose in the blood, either basally or during a glucose tolerance test. Its cause may vary from an autosomally transmitted genetic disorder to one associated with dysfunction of the proximal renal tubule (Fanconi syndrome, chronic kidney disease), or it may merely be a consequence of the increased load of glucose presented to the tubules by the elevated glomerular filtration rate during pregnancy. As many as 50% of pregnant women normally have demonstrable sugar in the urine, especially during the third and fourth months. This sugar is practically always glucose except during the late weeks of pregnancy, when lactose may be present.

Clinical Trials in Diabetes

Findings of the Diabetes Complications and Control Trial (DCCT) and of the United Kingdom Prospective Diabetes Study (UKPDS), have confirmed the beneficial effects of improved glycemic control in both type 1 and type 2 diabetes, respectively (see below). In addition, with increased understanding of the pathophysiology of both type 1 and type 2 diabetes, large prospective studies—Diabetes Prevention Trial 1 (DPT-1) and the Diabetes Prevention Program (DPP)—have been performed in attempts to prevent onset of these disorders (see below).

Clinical Trials in Type 1 Diabetes

Diabetes Prevention Trial-1

This multicenter study sponsored by the National Institutes of Health was designed to determine whether the development of type 1 diabetes mellitus could be prevented or delayed by immune intervention therapy. Daily low-dose insulin injections were administered for up to 8 years in first-degree relatives of type 1 diabetic patients who were selected as being at high risk for development of type 1 diabetes because of detectable islet cell antibodies and reduced early-insulin release. Unfortunately, this immune intervention failed to affect the onset of type 1 diabetes compared with a randomized untreated group. A related study using oral insulin in lower risk first-degree relatives who have islet cell antibodies but whose early insulin release remains intact also failed to show an effect on the onset of type 1 diabetes. After an average of 4.3 years of observation, type 1 diabetes developed in about 35% of persons in both the oral insulin and the placebo groups.

The Diabetes Control and Complications Trial

A long-term therapeutic study involving 1441 patients with type 1 diabetes mellitus reported that "near" normalization of blood glucose resulted in a delay in the onset and a major slowing of the progression of established microvascular and neuropathic complications of diabetes during a follow-up period of up to 10 years. Multiple insulin injections (66%) or insulin pumps (34%) were used in the intensively treated group, who were trained to modify their therapy in response to frequent glucose monitoring. The conventionally treated groups used no more than two insulin injections, and clinical well-being was the goal with no attempt to modify management based on HbA_{1c} determinations or the glucose results.

In half of the patients, a mean hemoglobin A_{1c} of 7.2% (normal: < 6%) and a mean blood glucose of 155 mg/dL were achieved using intensive therapy, while in the conventionally treated group HbA_{1c} averaged 8.9% with an average blood glucose of 225 mg/dL. Over the study period, which averaged 7 years, there was an approximately 60% reduction in risk between the two groups in regard to diabetic retinopathy, nephropathy, and neuropathy. The intensively treated group also had a nonsignificant reduction in the risk of macrovascular disease of 41% (95% CI, –10 to 68). Intensively treated patients had a threefold greater risk of serious hypoglycemia as well as a greater tendency toward weight gain. However, there were no deaths definitely attributable to hypoglycemia in any persons in the DCCT study, and no evidence of posthypoglycemic cognitive damage was detected.

Subjects participating in the DCCT study were subsequently enrolled in a follow-up observational study, the Epidemiology of Diabetes Interventions and Complications (EDIC) study. Even though the between-group differences in mean HbA_{1c} narrowed over 4 years, the group assigned to intensive therapy had a lower risk of retinopathy at 4 years and microalbuminuria at 7 to 8 years of continued study follow-up. Moreover, by the end of the 11-year follow-up period, the intensive therapy group had significantly reduced their risk of any cardiovascular disease events by 42% (95% CI, 9% to 23%; $P = 0.02$). Thus, it seems that the benefits of good glucose control persist even if control deteriorates at a later date.

The general consensus of the ADA is that intensive insulin therapy associated with comprehensive self-management training should become standard therapy in patients with type 1 diabetes mellitus after the age of puberty. Exceptions include those with advanced chronic kidney disease and the elderly, since in these groups the detrimental risks of hypoglycemia outweigh the benefits of tight glycemic control.

Immune Intervention Trials in New-Onset Type 1 Diabetes

At the time of diagnosis of type 1 diabetes, patients still have significant B cell function. This explains why soon after diagnosis patients go into a partial clinical remission ("honeymoon") requiring little or no insulin. This clinical remission is short-lived, however, and eventually patients lose all B cell function and have more labile glucose control. Attempts have been made to prolong this partial clinical remission using drugs such as cyclosporine, azathioprine, prednisone, and antithymocyte globulin. These drugs have had limited efficacy, and there are concerns about toxicity and the need for continuous treatment.

Newer agents that may induce immune tolerance and appear to have few side effects have been used in new-onset type 1 patients. Two studies with anti-CD3 antibodies have demonstrated that these agents can preserve endogenous insulin production. Larger phase 2 clinical trials are currently in progress.

Clinical Trials in Type 2 Diabetes

The Diabetes Prevention Program

This study was aimed at discovering whether treatment with either diet and exercise or metformin could prevent the onset of type 2 diabetes in people with impaired glucose tolerance; 3234 overweight men and women aged 25–85 years with impaired glucose tolerance participated in the study. Intervention with a low-fat diet and 150 minutes of moderate exercise (equivalent to a brisk walk) per week reduced the risk of progression to type 2 diabetes by 71% compared with a matched control group. Participants taking 80 mg of metformin twice a day reduced their risk of developing type 2 diabetes by 31%, but this intervention was relatively ineffective in those who were either less obese or in the older age group.

With the demonstration that intervention can be successful in preventing progression to diabetes in these subjects, a recommendation has been made to change the terminology from the less comprehensible "impaired glucose tolerance" to "prediabetes." The latter is a term that the public can better understand and thus respond to by implementing healthier diet and exercise habits.

See Related Guideline from *CURRENT Practice Guidelines in Primary Care 2009*

Kumamoto Study

The Kumamoto study involved a relatively small number of patients with type 2 diabetes (n = 110) who were nonobese and only slightly insulin-resistant, requiring less than 30 units of insulin per day for intensive therapy. Over a 6-year period, it was shown that intensive insulin therapy, achieving a mean HbA_{1c} of 7.1%, significantly reduced microvascular end points compared with conventional insulin therapy achieving a mean HbA_{1c} of 9.4%. Cardiovascular events were neither worsened nor improved by intensive therapy, and weight changes were likewise not influenced by either form of treatment.

The Veterans Administration Cooperative Study

This investigation involved 153 obese men who were moderately insulin-resistant and who were monitored for only 27 months. Intensive insulin treatment resulted in mean HbA_{1c} differences from conventional insulin treatment (7.2% versus 9.5%) that were comparable to those reported from the Kumamoto Study. However, a difference in cardiovascular outcome in this study has prompted some concern. While conventional insulin therapy resulted in 26 total cardiovascular events, there were 35 total cardiovascular events in the intensively treated group. This difference in the relatively small population was not statistically significant, but when the total events were broken down to *major* events (myocardial infarction, stroke, cardiovascular death, congestive heart failure, or amputation), the 18 major events in the group treated intensively with insulin were reported to be statistically greater ($P = .04$) than the ten major events occurring with conventional treatment. While this difference may be a chance consequence of studying too few patients for too short a time, it raises the possibility that insulin-resistant patients with visceral obesity and long-standing type 2 diabetes may develop a greater risk of serious cardiovascular mishap when intensively treated with high doses of insulin. At the end of the study, 64% of the intensively treated group were either receiving (1) an average of 113 units of insulin per day when only two injections per day were used or (2) a mean dosage of 133 units per day when multiple injections were used. Unfortunately, the UKPDS (see below), which did not discern any effect of intensive therapy on cardiovascular outcomes, does not resolve the concern generated by the Veterans Administration Study since their patient population consisted of newly diagnosed diabetic patients in whom the obese subgroup seemed to be less insulin-resistant, requiring a median insulin dose for intensive therapy of only 60 units per day by the twelfth year of the study.

The United Kingdom Prospective Diabetes Study

This multicenter study was designed to establish, in type 2 diabetic patients, whether the risk of macrovascular or microvascular complications could be reduced by intensive blood glucose control with oral hypoglycemic agents or insulin and whether any particular therapy was of advantage. A total of 3867 patients aged 25–65 years with newly diagnosed diabetes were recruited between 1977 and 1991, and studied over 10 years. The median age at baseline was 54 years; 44% were overweight (> 120% over ideal weight); and baseline HbA_{1c} was 9.1%. Therapies were randomized to include a control group on diet alone and separate groups intensively treated with either insulin or sulfonylurea (chlorpropamide, glyburide, or glipizide). Metformin was included as a randomization option in a subgroup of 342 overweight or obese patients, and much later in the study an additional subgroup of both normal-weight and overweight patients who were responding unsatisfactorily to sulfonylurea therapy were randomized to either continue on their sulfonylurea therapy alone or to have metformin combined with it.

Hypertension control substudy

In 1987, an additional modification was made to evaluate whether tight control of blood pressure with stepwise antihypertensive therapy would prevent macrovascular and microvascular complications in 758 hypertensive patients among this UKPDS population compared with 390 of them whose blood pressure was treated less intensively. The tight control group was randomly assigned to treatment with either an angiotensin-converting enzyme (ACE) inhibitor (captopril) or a beta-blocker (atenolol). Both drugs were stepped up to maximum dosages of 100 mg/d and then, if blood pressure remained higher than the target level of < 150/85 mm Hg, more drugs were added in the following stepwise sequence: a diuretic, slow-release nifedipine, methyldopa, and prazosin—until the target level of tight control was achieved. In the control group, hypertension was conventionally treated to achieve target levels < 180/105 mm Hg, but these patients were not prescribed either ACE inhibitors or beta-blockers.

Results of the UKPDS

Intensive treatment with either sulfonylureas, metformin, combinations of those two, or insulin achieved mean HbA_{1c} levels of 7%. This level of glycemic control decreases the risk of microvascular complications (retinopathy and nephropathy) in comparison with conventional therapy (mostly diet alone), which achieved mean levels of HbA_{1c} of 7.9%. Weight gain occurred in intensively treated patients except when metformin was used as monotherapy. No cardiovascular benefit and no adverse cardiovascular outcomes were noted regardless of the therapeutic agent. Hypoglycemic reactions occurred in the intensive treatment groups, but only one death from hypoglycemia was documented during 27,000 patient-years of intensive therapy.

When therapeutic subgroups were analyzed, some unexpected and paradoxical results were noted. Among the obese patients, intensive treatment with insulin or sulfonylureas did not reduce microvascular complications compared with diet therapy alone. This was in contrast to the significant benefit of intensive therapy with these drugs in the total group. Furthermore, intensive therapy with metformin was more beneficial in the overweight or obese persons than diet alone with regard to fewer myocardial infarctions, strokes, and diabetes-related deaths, but there was no significant reduction by metformin of diabetic microvascular complications as compared with the diet group. Moreover, in the subgroup of obese and nonobese patients in whom metformin was added to sulfonylurea failures, rather than showing a benefit, there was a 96% *increase* in diabetes-related deaths compared with the matched cohort of patients with unsatisfactory glycemic control on sulfonylureas who remained on their sulfonylurea therapy. Chlorpropamide also came out poorly on subgroup analysis in that those receiving it as intensive therapy did less well regarding progression to retinopathy than those conventionally treated with diet.

Intensive antihypertensive therapy to a mean of 144/82 mm Hg had beneficial effects on microvascular disease as well as on all diabetes-related end points, including virtually all cardiovascular outcomes, in comparison with looser control at a mean of 154/87 mm Hg. In fact, the advantage of reducing hypertension by this amount was substantially more impressive than the benefit achieved by improving the degree of glycemic control from a mean HbA_{1c} of 7.9% to 7%. More than half of the patients needed two or more drugs for adequate therapy of their hypertension, and there was no demonstrable advantage of ACE inhibitor therapy over therapy with beta-blockers with regard to diabetes end points. Use of a calcium channel blocker added to both treatment groups appeared to be safe over the long term in this diabetic population despite some controversy in the recent literature about its safety in diabetics.

Like the DCCT trialists, the UKPDS researchers performed post-trial monitoring to determine whether there were long-term benefits of having been in the intensively treated glucose and blood pressure arms of the study. The between-group differences in HbA_{1c} were lost within the first year of follow-up, but the reduced risk (24%, $P = 0.001$) of development or progression of microvascular complications in the intensively treated group persisted for 10 years. The intensively treated group also had significantly reduced risk of myocardial infarction (15%, $P = 0.01$) and death from any cause (13%, $P = 0.007$) during the follow-up period. The subgroup of overweight or obese subjects who were initially randomized to metformin therapy showed sustained reduction in risk of myocardial infarction and death from any cause in the follow-up period. The between-group blood pressure differences disappeared within 2 years of the end of the trial. Unlike the sustained benefits seen with glucose control, there were no sustained benefits from having been in the more tightly controlled blood pressure group. Both blood pressure groups were at similar risk for microvascular events and diabetes-related end points during the follow-up period.

Thus, the follow-up of the UKPDS type 2 diabetes cohort showed that, as in type 1 diabetes, the benefits of good glucose control persist even if control deteriorates at a later date. Blood pressure benefits, however, last only as long as the blood pressure is well controlled.

Implications of the UKPDS

It appears that glycemic control to levels of HbA_{1c} to 7% shows benefit in reducing total diabetes end points, including a 25% reduction in microvascular disease as compared with HbA_{1c} levels of 7.9%. This reassures those who have questioned whether the value of intensive therapy, so convincingly shown by the DCCT in type 1 diabetes, can safely be extrapolated to older patients with type 2 diabetes. It also argues against the concept of a "threshold" of glycemic control since in this group there was a benefit from this modest reduction of HbA_{1c} below 7.9% whereas in the DCCT a threshold was suggested in that further benefit was less apparent at HbA_{1c} levels below 8%.

Because of the complexity of the overall design in which many of the original therapy groups received additional medications to achieve glycemic goals but remained assigned to their group, statistical analysis may have been compromised by these multiple crossovers. For instance, in the diet group that was used as a control for all the drug treatment groups, only 58% of their total "patient-years" were actually drug-free while the remainder consisted of nonintensive therapy with various hypoglycemic drug regimens to avoid unacceptable hyperglycemia. This probably partly explains why the mean HbA_{1c} for this group was only 7.9% on "diet alone" therapy for over 10 years. In view of these crossovers within treatment groups, caution is suggested regarding several subgroup analyses that are controversial. These include the implication that metformin was superior to insulin or sulfonylureas in reducing diabetes-related end points in obese patients compared with diet therapy even though all three treatment groups achieved the same degree of glycemic control. Conversely, the finding of excess mortality in the subgroup of patients receiving combination therapy with metformin and sulfonylureas need not necessarily preclude this combination in patients doing poorly on sulfonylureas alone, although it certainly indicates a need for clarification of this important question.

Probably the most striking implication of the UKPDS is the benefit to the *hypertensive* type 2 diabetic patient of intensive control of blood pressure. There was no demonstrable advantage of ACE inhibitor therapy on outcome despite a number of short-term reports in smaller populations, implying that these drugs have special efficacy in reducing glomerular pressure beyond their general antihypertensive effects. Moreover, slow-release nifedipine showed no evidence of cardiac toxicity in this study despite some previous reports claiming that calcium channel blockers may be hazardous in patients with diabetes. Finally, the greater benefit in diabetes end points from antihypertensive than from antihyperglycemic treatments may be that the difference between the mean blood pressures achieved (144/82 mm Hg versus 154/87 mm Hg) is therapeutically more influential than the slight difference in HbA_{1c} (7% versus 7.9%). Greater hyperglycemia in the control group would most likely have rectified this discrepancy in outcomes. At present, the American Diabetes Association recommends vigorous treatment of both hyperglycemia and hypertension when they occur with an expectation that reductions in microvascular and cardiovascular outcomes will be additive.

The STENO-2 Study

The Steno-2 study was designed in 1990 to validate the efficacy of targeting multiple concomitant risk factors for both microvascular and macrovascular disorders in type 2 diabetes. A prospective, randomized, open, blinded end point design was used where 160 patients with type 2 diabetes and microalbuminuria were assigned to conventional therapy with their general practitioner or to intensive care at the Steno Diabetes Center. The intensively treated group had step-wise introduction of lifestyle and pharmacologic interventions aimed at keeping glycated hemoglobin less than 6.5%, blood pressure less than 130/80 mm Hg; total cholesterol < 175 mg/dL, and triglycerides < 150 mg/dL. All the intensively treated group received ACE inhibitors and if intolerant, an angiotensin II-receptor blocker. The lifestyle component of intensive intervention included reduction in dietary fat intake to less than 30% of total calories; smoking cessation program; light to moderate exercise; daily vitamin-mineral supplement of vitamin C, E, and chromium picolinate. Initially aspirin was only given as secondary prevention to patients with a history of ischemic cardiovascular disease; later all patients received aspirin. After a mean follow-up of 7.8 years, cardiovascular events (eg, myocardial infarction, angioplasties, coronary bypass grafts, strokes, amputations, vascular surgical interventions) developed in 44% of patients in the conventional arm and only in 24% in the intensive multifactorial arm—about a 50% reduction. Rates of nephropathy, retinopathy, and autonomic neuropathy were also lower in the multifactorial intervention arm by 62% and 63%, respectively.

The data from the UKPDS and this study provide support for guidelines recommending vigorous treatment of concomitant microvascular and cardiovascular risk factors in patients with type 2 diabetes.

ACCORD and ADVANCE studies

The ACCORD study was a randomized controlled study designed to determine whether normal HbA_{1c} levels would reduce the risk of cardiovascular events in middle-aged or older individuals with type 2 diabetes. About 35% of the 10,251 recruited subjects had established cardiovascular disease at study entry. The intensive arm of the study was discontinued after 3.5 years of follow-up because of more unexplained deaths in the intensive arm when compared with the control arm (22%, $P = 0.020$). Analysis of the data at time of discontinuation showed that the intensively treated group (mean HbA_{1c} 6.4%) had a 10% reduction in cardiovascular event rate compared with the standard treated group (mean HbA_{1c} 7.5%), but this difference was not statistically significant.

The ADVANCE trial randomly assigned 11,140 patients with type 2 diabetes to standard or intensive glucose control. The primary outcomes were major macrovascular cardiovascular events (nonfatal myocardial infarction or stroke or death from cardiovascular causes) or microvascular events. Overall, one-third (32%) of the subjects had established cardiovascular disease at study entry. After a median follow-up of 5 years, there was a nonsignificant reduction (6%) in major macrovascular event rate in the intensively treated group (mean HbA_{1c} 6.5%) compared with the standard therapy group (HbA_{1c} 7.3%).

Thus, the ACCORD and ADVANCE results do not provide support for the hypothesis that near-normal glucose control in patients with type 2 diabetes will reduce cardiovascular events. It is, however, important not to over-interpret the results of these two studies. The results do not exclude the possibility that cardiovascular benefits might accrue with longer duration of near-normal glucose control. In the UKPDS, risk reductions for myocardial infarction and death from any cause were only observed during 10 years of post-trial follow-up. Specific subgroups of type 2 diabetic patients may also have different outcomes. The ACCORD and ADVANCE studies recruited patients who had diabetes for 8–10 years and one-third of them already had established cardiovascular disease. Patients in the UKPDS, in contrast, had newly diagnosed diabetes and only 7.5% had a history of macrovascular disease. It is possible that the benefits of tight glycemic control on macrovascular events are attenuated in patients with longer duration of diabetes or with established vascular disease. Specific therapies used to lower glucose may also affect cardiovascular event rate or mortality. Severe hypoglycemia occurred more frequently in the intensively treated groups of the ACCORD and ADVANCE studies;

the ACCORD investigators were not able to exclude undiagnosed hypoglycemia as a potential cause for the increased death rate in the intensive treatment group.

Treatment Regimens

See Related Guideline from *CURRENT Practice Guidelines in Primary Care 2009*

Diet

A well-balanced, nutritious diet remains a fundamental element of therapy. The American Diabetes Association (ADA) recommends about 45–65% of total daily calories in the form of carbohydrates; 25–35% in the form of fat (of which less than 7% are from saturated fat), and 10–35% in the form of protein. In patients with type 2 diabetes, limiting the carbohydrate intake and substituting some of the calories with monounsaturated fats, such as olive oil, rapeseed (canola) oil, or the oils in nuts and avocados, can lower triglycerides and increase HDL cholesterol. Patients with type 1 diabetes or type 2 diabetes who take insulin should be taught "carbohydrate counting," so they can administer their insulin bolus for each meal based on its carbohydrate content. In obese individuals with diabetes, an additional goal is weight reduction by caloric restriction (see Chapter 29: Nutritional Disorders).

The current recommendations for both types of diabetes continue to limit cholesterol to 300 mg daily, and individuals with LDL cholesterol more than 100 mg/dL should limit dietary cholesterol to 200 mg daily. High protein intake may cause progression of kidney disease in patients with diabetic nephropathy; for these individuals, a reduction in protein intake to 0.8 kg/day (or about 10% of total calories daily) is recommended.

Exchange lists for meal planning can be obtained from the American Diabetes Association and its affiliate associations or from the American Dietetic Association, 216 W. Jackson Blvd., Chicago, IL 60606 (312-899-0040). Their Internet address is http://www.eatright.org.

Dietary fiber

Plant components such as cellulose, gum, and pectin are indigestible by humans and are termed dietary "fiber." Insoluble fibers such as cellulose or hemicellulose, as found in bran, tend to increase intestinal transit and may have beneficial effects on colonic function. In contrast, soluble fibers such as gums and pectins, as found in beans, oatmeal, or apple skin, tend to retard nutrient absorption rates so that glucose absorption is slower and hyperglycemia may be slightly diminished. Although its recommendations do not include insoluble fiber supplements such as added bran, the ADA recommends food such as oatmeal, cereals, and beans with relatively high soluble fiber content as staple components of the diet in diabetics. High soluble fiber content in the diet may also have a favorable effect on blood cholesterol levels.

Artificial and other sweeteners

Aspartame (NutraSweet) consists of two major amino acids, aspartic acid and phenylalanine, which combine to produce a sweetener 180 times as sweet as sucrose. A major limitation is that it is not heat stable, so it cannot be used in cooking. Saccharin (Sweet 'N Low), Sucralose (Splenda), and Acesulfame potassium (Sweet One) are other "artificial" sweeteners that can be used in cooking and baking.

Fructose represents a "natural" sugar substance that is a highly effective sweetener, induces only slight increases in plasma glucose levels, and does not require insulin for its metabolism. However, because of potential adverse effects of large amounts of fructose on raising serum cholesterol, triglycerides, and LDL cholesterol, it does not have any advantage as a sweetening agent in the diabetic diet. This does not preclude, however, ingestion of fructose-containing fruits and vegetables or fructose-sweetened foods in moderation.

Sugar alcohols, also known as polyols or polyalcohol, are commonly used as sweeteners and bulking agents. They occur naturally in a variety of fruits and vegetables but are also commercially made from sucrose, glucose, and starch. Examples are sorbitol, xylitol, mannitol, lactitol, isomalt, maltitol, and hydrogenated starch hydrolysates (HSH). They are not as easily absorbed as sugar, so they do not raise blood glucose levels as much. Therefore, sugar alcohols are often used in food products that are labeled as "sugar free," such as chewing gum, lozenges, hard candy, and sugar-free ice cream. However, if consumed in large quantities, they will raise blood glucose and can cause bloating and diarrhea.

Drugs for Treating Hyperglycemia

(Table 27–8.) The drugs for treating type 2 diabetes fall into several categories: (1) Drugs that primarily stimulate insulin secretion by binding to the sulfonylurea receptor. Sulfonylureas remain the most widely prescribed drugs for treating hyperglycemia. The meglitinide analog repaglinide and the D-phenylalanine derivative nateglinide also bind the sulfonylurea receptor and stimulate insulin secretion. (2) Drugs that alter insulin action: Metformin works in the liver. The thiazolidinediones appear to have their main effect on skeletal muscle and adipose tissue. (3) Drugs that principally affect absorption of glucose: The -glucosidase inhibitors acarbose and miglitol are such currently available drugs. (4) Drugs that mimic incretin effect or prolong incretin action: Exenatide and DPP 1V inhibitors fall into this category. (5) Other: Pramlintide lowers glucose by suppressing glucagon and slowing gastric emptying.

Table 27–8. Drugs for treatment of type 2 diabetes mellitus.

Drug	**Tablet size**	**Daily Dose**	**Duration of Action**
Sulfonylureas			
Tolbutamide (Orinase)	500 mg	0.5–2 g in two or three divided doses	6–12 hours
Tolazamide (Tolinase)	100, 250, and 500 mg	0.1–1 g as single dose or in two divided doses	Up to 24 hours
Acetohexamide (Dymelor)[2]	250 and 500 mg	0.25–1.5 g as single dose or in two divided doses	8–24 hours
Chlorpropamide (Diabinese)[2]	100 and 250 mg	0.1–0.5 g as single dose	24–72 hours
Glyburide			

(DiaBeta, Micronase)	1.25, 2.5, and 5 mg	1.25–20 mg as single dose or in two divided doses	Up to 24 hours
(Glynase)	1.5, 3, and 6 mg	1.5–12 mg as single dose or in two divided doses	Up to 24 hours
Glipizide			
(Glucotrol)	5 and 10 mg	.5–20 mg twice a day 30 minutes before meals	6–12 hours
(Glucotrol XL)	2.5, 5, and 10 mg	2.5 to 10 mg once a day is usual dose; 20 mg once a day is maximal dose	Up to 24 hours
Gliclazide (not available in US)	80 mg	40–80 mg as single dose; 160–320 mg as divided dose	12 hours
Glimepiride (Amaryl)	1, 2, and 4 mg	1–4 mg once a day is usual	Up to 24 hours

		dose; 8 mg once a day is maximal dose	
Meglitinide analogs			
Repaglinide (Prandin)	0.5, 1, and 2 mg	0.5 to 4 mg three times a day before meals	3 hours
D-Phenylalanine derivative			
Nateglinide (Starlix)	60 and 120 mg	60 or 120 mg three times a day before meals	1.5 hours
Biguanides			
Metformin (Glucophage)	500, 850, and 1000 mg	1–2.5 g; 1 tablet with meals two or three times daily	7–12 hours
Extended-release metformin (Glucophage XR)	500 mg	500–2000 mg once a day	Up to 24 hours
Thiazolidinediones			

Rosiglitazone (Avandia)	2, 4, and 8 mg	4–8 mg daily (can be divided)	Up to 24 hours
Pioglitazone (Actos)	15, 30, and 45 mg	15–45 mg daily	Up to 24 hours
-Glucosidase inhibitors			
Acarbose (Precose)	50 and 100 mg	25 to 100 mg three times a day just before meals	4 hours
Miglitol (Glyset)	25, 50, and 100 mg	25–100 mg three times a day just before meals	4 hours
Incretins			
Exenatide (Byetta)	1.2 mL and 2.4 mL prefilled pens containing 5 mcg and 10 mcg (subcutaneous injection)	5 mcg subcutaneously twice a day within 1 hour of breakfast and dinner. Increase to 10 mcg subcutaneously twice a day	6 hours

		after about a month. Do not use if calculated creatinine clearance is less than 30 mL/min.	
Sitagliptin (Januvia)	25, 50, and 100 mg	100 mg once daily is usual dose; dose is 50 mg once daily if calculated creatinine clearance is 30 to 50 mL/min and 25 mg once daily if clearance is less than 30 mL/min.	24 hours
Others			
Pramlintide (Symlin)	5 mL vial containing 0.6 mg/mL;	For insulin-treated type 2 patients, start	

	also available as prefilled pens. Symlin pen 60 or Symlin pen 120 (subcutaneous injection)	at 60 mcg dose three times a day (10 units on U100 insulin syringe). Increase to 120 mcg three times a day (20 units on U100 insulin syringe) if no nausea for 3–7 days. Give immediately before meal. For type 1 patients, start at 15 mcg three times a day (2.5 units on U100 insulin syringe) and increase by increments of 15 mcg to a	

		maximum of 60 mcg three times a day, as tolerated. To avoid hypoglycemia, lower insulin dose by 50% on initiation of therapy.	

Drugs that primarily stimulate insulin secretion by binding to the sulfonylurea on the beta cell

Sulfonylureas

The primary mechanism of action of the sulfonylureas is to stimulate insulin release from pancreatic B cells. Specific receptors on the surface of pancreatic B cells bind sulfonylureas in the rank order of their insulinotropic potency (glyburide with the greatest affinity and tolbutamide with the least affinity). It has been shown that activation of these receptors closes potassium channels, resulting in depolarization of the B cell. This depolarized state permits calcium to enter the cell and actively promote insulin release.

Sulfonylureas are not indicated for use in type 1 diabetes patients since these drugs require functioning pancreatic

B cells to produce their effect on blood glucose. These drugs are used in patients with type 2 diabetes, in whom acute administration improves the early phase of insulin release that is refractory to acute glucose stimulation. Sulfonylureas are metabolized by the liver and apart from acetohexamide, whose metabolite is more active than the parent compound, the metabolites of all the other sulfonylureas are weakly active or inactive. The metabolites are excreted by the kidney and, in the case of the second-generation sulfonylureas, partly excreted in the bile. Sulfonylureas are generally contraindicated in patients with severe liver or kidney impairment. Idiosyncratic reactions are rare, with skin rashes or hematologic toxicity (leukopenia, thrombocytopenia) occurring in less than 0.1% of users.

First-generation sulfonylureas (tolbutamide, tolazamide, acetohexamide, chlorpropamide)

Tolbutamide is supplied as 500-mg tablets. It is rapidly oxidized in the liver to inactive metabolites, and its approximate duration of effect is relatively short (6–10 hours). Tolbutamide is probably best administered in divided doses (eg, 500 mg before each meal and at bedtime); however, some patients require only one or two tablets daily with a maximum dose of 3000 mg/d. Because of its short duration of action, which is independent of kidney function, tolbutamide is probably the safest sulfonylurea to use if liver function is normal. Prolonged hypoglycemia has been reported rarely with tolbutamide, mostly in patients receiving certain antibacterial sulfonamides (sulfisoxazole), phenylbutazone for arthralgias, or the oral azole antifungal drugs to treat candidiasis. These drugs apparently compete with tolbutamide for oxidative enzyme systems in the liver, resulting in maintenance of high levels of unmetabolized, active sulfonylurea in the circulation.

Tolazamide, acetohexamide, and chlorpropamide are rarely used. Chlorpropamide has a prolonged biologic effect, and severe hypoglycemia can occur especially in the elderly as their renal clearance declines with aging. Its other side effects include alcohol-induced flushing and hyponatremia due to its effect on vasopressin secretion and action.

Second-generation sulfonylureas (glyburide, glipizide, gliclazide, glimepiride)

Glyburide, glipizide, gliclazide, and glimepiride are 100–200 times more potent than tolbutamide. These drugs should be used with caution in patients with cardiovascular disease or in elderly patients, in whom prolonged hypoglycemia would be especially dangerous.

Glyburide is available in 1.25-mg, 2.5-mg, and 5-mg tablets. The usual starting dose is 2.5 mg/d, and the average maintenance dose is 5–10 mg/d given as a single morning dose; maintenance doses higher than 20 mg/d are not recommended. Some reports suggest that 10 mg is a maximum daily therapeutic dose, with 15–20 mg having no additional benefit in poor responders and doses over 20 mg actually worsening hyperglycemia. Glyburide is metabolized in the liver into products with hypoglycemic activity, which probably explains why assays specific for the unmetabolized compound suggest a plasma half-life of only 1–2 hours, yet the biologic effects of glyburide are clearly persistent 24 hours after a single morning dose in diabetic patients. Glyburide is unique among sulfonylureas in that it not only binds to the pancreatic B cell membrane sulfonylurea receptor but also becomes sequestered within the B cell. This may also contribute to its prolonged biologic effect despite its relatively short circulating half-life. A "Press Tab" formulation of "micronized" glyburide—easy to divide in half with slight pressure if necessary—is available in tablet sizes of 1.5 mg, 3 mg, and 6 mg.

Glyburide has few adverse effects other than its potential for causing hypoglycemia, which at times can be prolonged. Flushing has rarely been reported after ethanol ingestion. It does not cause water retention, as chlorpropamide does, but rather slightly enhances free water clearance. Glyburide is absolutely contraindicated in the presence of hepatic impairment and should not be used in patients with chronic kidney disease, in elderly patients, or in those who would be put at serious risk from an episode of hypoglycemia.

Glipizide is available in 5-mg and 10-mg tablets. For maximum effect in reducing postprandial hyperglycemia, this agent should be ingested 30 minutes before meals, since rapid absorption is delayed when the drug is taken with food. The recommended starting dose is 5 mg/d, with up to 15 mg/d given as a single daily dose before breakfast. When higher daily doses are required, they should be divided and given before meals. The maximum dose recommended by the manufacturer is 40 mg/d, although doses above 10–15 mg probably provide little additional benefit in poor responders and may even be *less* effective than smaller doses.

At least 90% of glipizide is metabolized in the liver to inactive products, and 10% is excreted unchanged in the urine. Glipizide therapy is therefore contraindicated in patients with liver or kidney impairment, who would be at high risk for hypoglycemia; but because of its lower potency and shorter duration of action, it is preferable to glyburide in elderly patients. Glipizide has also been marketed as Glucotrol-XL in 5-mg and 10-mg tablets. It provides extended release during transit through the gastrointestinal tract with greater effectiveness in lowering prebreakfast hyperglycemia than the shorter-duration immediate-release standard glipizide tablets. However, this formulation appears to have sacrificed its lower propensity for severe hypoglycemia compared with longer-acting glyburide without showing any demonstrable therapeutic advantages over glyburide.

Gliclazide (not available in the United States) is another intermediate duration sulfonylurea with a duration of action of about 12 hours. It is available as 80 mg tablets. The recommended starting dose is 40–80 mg/d with a maximum dose of 320 mg. Doses of 160 mg and above are given as divided doses before breakfast and dinner. The drug is metabolized by the liver; the metabolites and conjugates have no hypoglycemic effect. An extended release preparation is available.

Glimepiride is given once daily as monotherapy or in combination with insulin to lower blood glucose in diabetes patients who cannot control their glucose level through diet and exercise. Glimepiride achieves blood glucose lowering with the lowest dose of any sulfonylurea compound, and this tends to increase its cost-effectiveness. A single daily dose of 1 mg/d has been shown to be effective, and the maximal recommended dose is 8 mg. It has a long duration of action with a pharmacodynamic half-life of 5 hours, allowing once-daily administration, which improves compliance. It is completely metabolized by the liver to relatively inactive metabolic products.

Meglitinide analogs

Repaglinide is structurally similar to glyburide but lacks the sulfonic acid-urea moiety. It acts by binding to the sulfonylurea receptor and closing the ATP-sensitive potassium channel. It is rapidly absorbed from the intestine and then undergoes complete metabolism in the liver to inactive biliary products, giving it a plasma half-life of less than 1 hour. The drug therefore causes a brief but rapid pulse of insulin. The starting dose is 0.5 mg three times a day 15 minutes before each meal. The dose can be titrated to a maximal daily dose of 16 mg. Like the sulfonylureas, repaglinide can be used in combination with metformin. Hypoglycemia is the main side effect. In clinical trials, when the drug was compared with a long-duration sulfonylurea (glyburide), there was a trend toward less hypoglycemia. Like the sulfonylureas also, repaglinide causes weight gain. Metabolism is by cytochrome P450 3A4 isoenzyme, and other drugs that induce or inhibit this isoenzyme may increase or inhibit (respectively) the metabolism of repaglinide. The drug may be useful in patients with kidney impairment or in the elderly.

D-Phenylalanine derivative

Nateglinide stimulates insulin secretion by binding to the sulfonylurea receptor and closing the ATP-sensitive potassium channel. This compound is rapidly absorbed from the intestine, reaching peak plasma levels within 1 hour. It is metabolized in the liver and has a plasma half-life of about 1.5 hours. Like repaglinide, it causes a brief rapid pulse of insulin, and when given before a meal it reduces the postprandial rise in blood glucose. The drug is available as 60-mg and 120-mg tablets. The 60-mg dose is used in patients who have mild elevations in HbA_{1c}. For most patients, the recommended starting and maintenance dose is 120 mg three times a day before meals. Like the other insulin secretagogues, its main side effects are hypoglycemia and weight gain.

Drugs that alter insulin action

Metformin

Metformin (1,1-dimethylbiguanide hydrochloride) is used, either alone or in conjunction with other oral agents or insulin, in the treatment of patients with type 2 diabetes.

Metformin's primary action is on the liver, reducing hepatic gluconeogenesis by activating adenosine monophosphate-activated protein kinase (AMPK), which acts as an intracellular energy sensor, and has a critical role regulating gluconeogenesis. LKB1 is a protein threonine kinase that phosphorylates and activates AMPK; it was recently reported that in mice the deletion of LKB1 function in the liver results in hyperglycemia with increased gluconeogenic and lipogenic gene expression. The deletion of LKB1 also eliminated the glucose lowering effect of metformin, providing genetic proof for the hypothesis that metformin lowers glucose levels by AMP kinase activation.

Metformin has a half-life of 1.5–3 hours, is not bound to plasma proteins, and is not metabolized in humans, being excreted unchanged by the kidneys.

Metformin may be used as an adjunct to diet for the control of hyperglycemia and its associated symptoms in patients with type 2 diabetes, particularly those who are obese or are not responding optimally to maximal doses of sulfonylureas. A side benefit of metformin therapy is its tendency to improve both fasting and postprandial hyperglycemia and hypertriglyceridemia in obese diabetics without the weight gain associated with insulin or sulfonylurea therapy. Metformin is not indicated for patients with type 1 diabetes and is contraindicated in diabetics with serum creatinine levels of 1.5 mg/dL or higher, hepatic insufficiency, alcoholism, or a propensity to develop tissue hypoxia.

Metformin is dispensed as 500 mg, 850 mg, and 1000 mg tablets. A 500 mg extended-release preparation is also available. Although the maximal dosage is 2.55 g, little benefit is seen above a total dose of 2000 mg. It is important to begin with a low dose and increase the dosage very gradually in divided doses—taken with meals—to reduce minor gastrointestinal upsets. A common schedule would be one 500 mg tablet three times a day with meals or one 850 mg or 1000 mg tablet twice daily at breakfast and dinner. One to four tablets of the extended-release preparation can be given once a day.

The most frequent side effects of metformin are gastrointestinal symptoms (anorexia, nausea, vomiting, abdominal discomfort, diarrhea), which occur in up to 20% of patients. These effects are dose-related, tend to occur at onset of therapy, and often are transient. However, in 3–5% of patients, therapy may have to be discontinued because of persistent diarrheal discomfort. In a retrospective analysis, it has been reported that patients switched from immediate-release metformin to a comparable dose of extended-release metformin experienced fewer gastrointestinal side effects.

Hypoglycemia does not occur with therapeutic doses of metformin, which permits its description as a "euglycemic" or "antihyperglycemic" drug rather than an oral hypoglycemic agent. Dermatologic or hematologic toxicity is rare.

Lactic acidosis has been reported as a side effect but is uncommon with metformin in contrast to phenformin. While therapeutic doses of metformin reduce lactate uptake by the liver, serum lactate levels rise only minimally if at all, since other organs such as the kidney can remove the slight excess. However, if tissue hypoxia occurs, the metformin-treated patient is at higher risk for lactic acidosis due to compromised lactate removal. Similarly, when kidney function deteriorates, affecting not only lactate removal by the kidney but also metformin excretion, plasma levels of metformin rise far above the therapeutic range and block hepatic uptake enough to provoke lactic acidosis without associated increases in lactic acid production. Almost all reported cases have involved subjects with associated risk factors that should have contraindicated its use (kidney, liver, or cardiorespiratory insufficiency, alcoholism, advanced age). Acute kidney failure can occur rarely in certain patients receiving radiocontrast agents. Metformin therapy should therefore be temporarily halted on the day of the test and for 2 days following injection of radiocontrast agents to avoid potential lactic acidosis if end-stage chronic kidney failure occurs.

Thiazolidinediones

Drugs of this class of antihyperglycemic agents sensitize peripheral tissues to insulin. They bind a nuclear receptor called peroxisome proliferator-activated receptor gamma

(PPAR-) and affect the expression of a number of genes and regulate the release of the adipokines—resistin and adiponectin—from adipocytes. Adiponectin secretion is stimulated, which sensitizes tissues to the effects of insulin, and resistin secretion is inhibited, which reduces insulin resistance. Observed effects of thiazolidinediones include increased glucose transporter expression (GLUT 1 and GLUT 4), decreased free fatty acid levels, decreased hepatic glucose output, and increased differentiation of preadipocytes into adipocytes. Like the biguanides, this class of drugs does not cause hypoglycemia.

Two drugs of this class, rosiglitazone and pioglitazone, are available for clinical use. Both are effective as monotherapy and in combination with sulfonylureas or metformin or insulin. When used as monotherapy, these drugs lower HbA_{1c} by about 1 or 2 percentage points. When used in combination with insulin, they can result in a 30–50% reduction in insulin dosage, and some patients can come off insulin completely. The dosage of rosiglitazone is 4–8 mg daily and of pioglitazone, 15–45 mg daily, and the drugs do not have to be taken with food. Rosiglitazone is primarily metabolized by the CYP 2C8 isoenzyme and pioglitazone is metabolized by CYP 2C8 and CYP 3A4.

The combination of a thiazolidinedione and metformin has the advantage of not causing hypoglycemia. Patients inadequately managed on sulfonylureas can do well on a combination of sulfonylurea and rosiglitazone or pioglitazone. About 25% of patients in clinical trials fail to respond to these drugs, presumably because they are significantly insulinopenic.

These drugs have some additional effects apart from glucose lowering. Rosiglitazone therapy is associated with increases in total cholesterol, LDL-cholesterol (15%), and HDL-cholesterol (10%). There is a reduction in free fatty acids of about 8–15%. The changes in triglycerides were generally not different from placebo. Pioglitazone in clinical trials lowered triglycerides (9%) and increased HDL-cholesterol (15%), but did not cause a consistent change in total cholesterol and LDL-cholesterol levels. A prospective randomized comparison of the metabolic effects of pioglitazone and rosiglitazone on patients who had previously taken troglitazone (now withdrawn from the US market) showed similar effects on HbA_{1c} and weight gain. Pioglitazone-treated persons, however, had lower total cholesterol, LDL-cholesterol, and triglycerides when compared with rosiglitazone-treated persons. The thiazolidinediones have also been demonstrated to decrease levels of plasminogen activator inhibitor type 1, matrix metalloproteinase 9, C-reactive protein, and interleukin 6. Small prospective studies have demonstrated that treatment with these drugs leads to improvements in the biochemical and histologic features of nonalcoholic fatty liver disease. The thiazolidinediones also may limit vascular smooth muscle proliferation after injury, and there are reports that pioglitazone and troglitazone (subsequently withdrawn from the US market) reduced neointimal proliferation after coronary stent placement. Finally, in one double-blind, placebo-controlled study, rosiglitazone was shown to be associated with a decrease in the ratio of urinary albumin to creatinine excretion.

Safety concerns and some troublesome side effects have emerged about this class of drugs that potentially limit their use.

A meta-analysis of 42 randomized clinical trials with rosiglitazone suggested that this drug increases the risk of angina pectoris or myocardial infarction. Even though definitive evidence is lacking, the FDA has required the manufacturer to include a boxed warning about the potential risk of heart attacks on the drug label. A meta-analysis of clinical trials with pioglitazone did not show a similar finding. Many physicians, because of these findings, have stopped prescribing rosiglitazone and instead use pioglitazone, if indicated.

Edema occurs in about 3–4% of patients receiving monotherapy with rosiglitazone or pioglitazone. The edema occurs more frequently (10–15%) in patients receiving concomitant insulin therapy and may result in congestive heart failure. The drugs are contraindicated in diabetic individuals with New York Heart Association class III and IV cardiac status. Thiazolidinediones have also been reported as being associated with new onset or worsening macular edema. Apparently, this is a rare side effect, and most of these patients also had peripheral edema. The macular edema resolved or improved once the drug was discontinued.

In experimental animals, rosiglitazone stimulates bone marrow adipogenesis at the expense of osteoblastogenesis resulting in a decrease in bone density. An increase in fracture risk in women (but not men) has been reported with both rosiglitazone and pioglitazone. The fracture risk is in the range of 1.9 per 100 patient-years with the thiazolidinedione compared to 1.1 per 100 patient years on comparison treatment. In at least one study of rosiglitazone, the fracture risk was increased in premenopausal as well as postmenopausal women.

Other side effects include anemia, which occurs in 4% of patients treated with these drugs; it may be due to a dilutional effect of increased plasma volume rather than a reduction in red cell mass. Weight gain occurs, especially when the drug is combined with a sulfonylurea or insulin. Some of the weight gain is fluid retention, but there is also an increase in total fat mass.

Troglitazone, the first drug in this class to go into widespread clinical use, was withdrawn from clinical use because of drug-associated fatal liver failure. The two currently available agents, rosiglitazone and pioglitazone, have thus far not caused hepatotoxicity. The FDA has, however, recommended that patients should not initiate drug therapy if there is clinical evidence of active liver disease or pre-treatment elevation of the alanine aminotransferase (ALT) level that is 2.5 times greater than the upper limit of normal. Obviously, caution should be used in initiation of therapy in patients with even mild ALT elevations. Liver biochemical tests should be performed prior to initiation of treatment and periodically thereafter.

Drugs that affect absorption of glucose

-Glucosidase inhibitors competitively inhibit the -glucosidase enzymes in the gut that digest dietary starch and sucrose. Two of these drugs—acarbose and miglitol—are available for clinical use. Both are potent inhibitors of glucoamylase, -amylase, and sucrase but have less effect on isomaltase and hardly any on trehalase and lactase. Acarbose binds 1000 times more avidly to the intestinal disaccharidases than do products of carbohydrate digestion or sucrose. A fundamental difference between acarbose and miglitol is in their absorption. Acarbose has the molecular mass and structural features of a tetrasaccharide, and very little (about 2%) crosses the microvillar membrane. Miglitol, however, has a structural similarity with glucose and is absorbable. Both drugs delay the absorption of carbohydrate and lower postprandial glycemic excursion.

Acarbose

Acarbose is available as 50-mg and 100-mg tablets. The recommended starting dose of acarbose is 50 mg twice daily, gradually increasing to 100 mg three times daily. For maximal benefit on postprandial hyperglycemia, acarbose should be given with the first mouthful of food ingested. In diabetic patients, it reduces postprandial hyperglycemia by 30–50%, and its overall effect is to lower the HbA_{1c} by 0.5–1%.

The principal adverse effect, seen in 20–30% of patients, is flatulence. This is caused by undigested carbohydrate reaching the lower bowel, where gases are produced by bacterial flora. In 3% of cases, troublesome diarrhea occurs. This gastrointestinal discomfort tends to discourage excessive carbohydrate consumption and promotes improved compliance of type 2 patients with their diet prescriptions. When acarbose is given alone, there is no risk of hypoglycemia. However, if combined with insulin or sulfonylureas, it might increase the risk of hypoglycemia from these agents. A slight rise in hepatic aminotransferases has been noted in clinical trials with acarbose (5% versus 2% in placebo controls, and particularly with doses > 300 mg/d). The levels generally return to normal on stopping the drug.

In the UKPDS, approximately 2000 patients on diet, sulfonylurea, metformin, or insulin therapy were randomized to acarbose or placebo therapy. By 3 years, 60% of the patients had discontinued the drug, mostly because of gastrointestinal symptoms. If one looked only at the 40% who remained on the drug, they had an 0.5% lower HbA_{1c} compared with placebo.

Miglitol

Miglitol is similar to acarbose in terms of its clinical effects. It is indicated for use in diet- or sulfonylurea-treated patients with type 2 diabetes. Therapy is initiated at the lowest effective dosage of 25 mg three times a day. The usual maintenance dose is 50 mg three times a day, although some patients may benefit from increasing the dose to 100 mg three times a day. Gastrointestinal side effects occur as with acarbose. The drug is not metabolized and is excreted unchanged by the kidney. Theoretically, absorbable -glucosidase inhibitors could induce a deficiency of one or more of the -glucosidases involved in cellular glycogen metabolism and biosynthesis of glycoproteins. This does not occur in practice because, unlike the intestinal mucosa, which sees a high concentration of the drug, the blood level is 200-

fold to 1000-fold lower than the concentration needed to inhibit intracellular -glucosidases. Miglitol should not be used in end-stage chronic kidney disease, when its clearance would be impaired.

Incretins

Oral glucose provokes a threefold to fourfold higher insulin response than an equivalent dose of glucose given intravenously. This is because the oral glucose causes a release of gut hormones, principally glucagon-like peptide 1 (GLP-1) and glucose-dependent insulinotropic polypeptide (GIP1), that amplify the glucose-induced insulin release. This "incretin effect" is reduced in patients with type 2 diabetes. GLP-1 secretion (but not GIP1 secretion) is impaired in patients with type 2 diabetes and when GLP-1 is infused in patients with type 2 diabetes, it stimulates insulin secretion and lowers glucose levels. GLP-1, unlike the sulfonylureas, has only a modest insulin stimulatory effect at normoglycemic concentrations. This means that GLP-1 has a lower risk for hypoglycemia than the sulfonylureas.

In addition to its insulin stimulatory effect, GLP-1 also has a number of other pancreatic and extrapancreatic effects. It suppresses glucagon secretion and so may ameliorate the hyperglucagonemia that is present in people with diabetes and improve postprandial hyperglycemia. GLP-1 preserves islet integrity and reduces apoptotic cell death of human islet cells in culture. In mice, streptozotocin-induced apoptosis is significantly reduced by coadministration of exendin-4 or exenatide, a GLP-1 receptor agonist. GLP-1 acts on the stomach delaying gastric emptying; the importance of this effect on glucose lowering is illustrated by the observation that antagonizing the deceleration of gastric emptying markedly reduces the glucose lowering effect of GLP-1. GLP-1 receptors are present in the central nervous system, and intracerebroventricular administration of GLP-1 in wild type mice, but not in GLP-1 receptor knockout mice, inhibits feeding. Type 2 diabetic patients undergoing GLP-1 infusion are less hungry; it is unclear whether this is mainly due to a deceleration of gastric emptying or whether there is a central nervous system effect as well.

Exenatide

GLP-1 is rapidly proteolyzed by dipeptidyl peptidase 4 (DPP-4), and therefore for clinical effect would need to be administered as a continuous infusion. Exendin 4 or exenatide is a GLP-1 receptor agonist isolated from the saliva of the Gila Monster (a venomous lizard) that is more resistant to DPP-4 action and so its half-life is 2.4 hours and its glucose lowering effect is about 6 hours. When this drug is given to patients with type 2 diabetes by subcutaneous injection twice daily, it lowers blood glucose and HbA_{1c} levels. Exenatide appears to have the same effects as GLP-1 on glucagon suppression and gastric emptying. In clinical trials, adding exenatide therapy to patients with type 2 diabetes already taking metformin or a sulfonylurea, or both, further lowered the HbA_{1c} value by 0.4% to 0.6% over a 30-week period. These patients also experienced a weight loss of 3–6 pounds. In an open label extension study up to 80 weeks, the HbA_{1c} reduction was sustained and there was further weight loss (to a total loss of about 10 pounds). The main side effect was nausea, affecting over 40% of the patients. The nausea was dose-dependent and declined with time. The risk of hypoglycemia was higher in persons taking sulfonylureas. The FDA has received 30 post-marketing reports of acute pancreatitis in patients taking exenatide. Many of these patients had other risk factors for pancreatitis, but the possibility remains that the drug was causally responsible for some cases. Patients taking exenatide should be advised to seek immediate medical care if they experience unexplained persistent severe abdominal pain. The delay in gastric emptying may affect the absorption of some other drugs; therefore, antibiotics and oral contraceptives should be taken 1 hour before exenatide doses. Low-titer antibodies against exenatide develop in over one-third (38%) of patients, but the clinical effects are not attenuated. High-titer antibodies develop in a subset of patients (~6%), and in about half of these cases, an attenuation of glycemic response has been seen.

Exenatide is dispensed as two fixed-dose pens (5 mcg and 10 mcg). It is injected 60 minutes before breakfast and before dinner. Patients should be prescribed the 5 mcg pen for the first month and, if tolerated, the dose can then be increased to 10 mcg twice a day. The drug is not recommended in patients with glomerular filtration rate less than 30 mL/min.

Sitagliptin

The oral DPP-4 inhibitors prolong the action of endogenously released GLP-1 and GIP. A number of neuropeptides, growth factors, cytokines, and chemokines are potential DPP-4 substrates; DPP-4 inhibitors prolong the actions of neuropeptide Y and substance P. Sitagliptin in clinical trials was shown to be effective in lowering glucose when used alone and in combination with metformin and pioglitazone. In various clinical trials, improvements in HbA_{1c} ranged from 0.5% to 1.4%. The usual dose of sitagliptin is 100 mg once daily, but the dose is reduced to 50 mg daily if the calculated creatinine clearance is 30–50 mL/min and to 25 mg for clearances less than 30 mL/min. Unlike exenatide, sitagliptin does not cause nausea or vomiting. It also does not result in weight loss. The main adverse effect appears to be a predisposition to nasopharyngitis or upper respiratory tract infection. A small increase in neutrophil count of

~200 cells/mcL has also occurred. Since its FDA approval and clinical use, there have been reports of serious allergic reactions to sitagliptin, including anaphylaxis, angioedema, and exfoliative skin conditions including Stevens-Johnson syndrome. The frequency of these events is unclear.

Others

Pramlintide is a synthetic analog of islet amyloid polypeptide (IAPP or amylin). When given subcutaneously, it delays gastric emptying, suppresses glucagon secretion, and decreases appetite. It is approved for use both in type 1 diabetes and in insulin-treated type 2 diabetes. In 6-month clinical studies with type 1 and insulin-treated type 2 patients, those on the drug had an approximately 0.4% reduction in HbA_{1c} and about 1.7 kg weight loss compared with placebo. The HbA_{1c} reduction was sustained for 2 years but some of the weight was regained. The drug is given by injection immediately before the meal. Hypoglycemia can occur, and it is recommended that the short-acting or premixed insulin doses be reduced by 50% when the drug is started. Nausea was the other main side effect, affecting 30–50% of persons but tended to improve with time. In patients with type 1 diabetes, the initial dose of pramlintide is 15 mcg before each meal and titrated up by 15 mcg increments to a maintenance dose of 30 mcg or 60 mcg before each meal. In patients with type 2 diabetes, the starting dose is 60 mcg premeals increased to 120 mcg in 3 to 7 days if no significant nausea occurs.

Drug combinations

Several drug combinations are available in different dose sizes, including glyburide and metformin (Glucovance); glipizide and metformin (Metaglip); rosiglitazone and metformin (Avandamet); pioglitazone and metformin (ACTOplus Met); rosiglitazone and glimepiride (Avandaryl); pioglitazone and glimepiride (Duetact); and sitagliptin and metformin (Janumet). These drug combinations, however, limit the clinician's ability to optimally adjust dosage of the individual drugs and for that reason are not recommended.

Safety of the antihyperglycemic agents

The UKPDS has put to rest previous concerns regarding the safety of sulfonylureas. It did not confirm any cardiovascular hazard among over 1500 patients treated intensively with sulfonylureas for over 10 years, compared with a comparable number who received either insulin or diet therapy. Analysis of a subgroup of obese patients receiving metformin also showed no hazard and even a slight reduction in cardiovascular deaths compared with conventional therapy.

The currently available thiazolidinediones have not to date exhibited the idiosyncratic hepatotoxicity seen with troglitazone. However, these drugs can precipitate congestive heart failure and should not be used in patients with New York Heart Association class III and IV cardiac status. Lactic acidosis from metformin (see above) is quite rare and probably not a major problem with its use in the absence of major risk factors such as impaired kidney or liver function or conditions predisposing to hypoxia.

Insulin

Insulin is indicated for type 1 diabetes as well as for type 2 diabetic patients with insulinopenia whose hyperglycemia does not respond to diet therapy either alone or combined with other hypoglycemic drugs.

With the development of highly purified human insulin preparations, immunogenicity has been markedly reduced, thereby decreasing the incidence of therapeutic complications such as insulin allergy, immune insulin resistance, and localized lipoatrophy at the injection site. However, the problem of achieving optimal insulin delivery remains unsolved with the present state of technology. It has not been possible to reproduce the physiologic patterns of intraportal insulin secretion with subcutaneous injections of short-acting or longer-acting insulin preparations. Even so, with the help of appropriate modifications of diet and exercise and careful monitoring of capillary blood glucose levels at home, it has often been possible to achieve acceptable control of blood glucose by using various mixtures of short- and longer-acting insulins injected at least twice daily or portable insulin infusion pumps.

Characteristics of available insulin preparations

Commercial insulin preparations differ with respect to the time of onset and duration of their biologic action (Table 27–9).

Table 27–9. Summary of bioavailability characteristics of the insulins.

Insulin Preparations	**Onset of Action**	**Peak Action**	**Effective Duration**
Insulins lispro, aspart, glulisine	5–15 minutes	1–1.5 hours	3–4 hours
Human regular	30–60 minutes	2 hours	6–8 hours
Human NPH	2–4 hours	6–7 hours	10–20 hours
Insulin glargine	1.5 hours	Flat	~24 hours
Insulin detemir	1 hour	Flat	17 hours

Species of insulin

Human insulin is produced by recombinant DNA techniques (biosynthetic human insulin) as Humulin (Eli Lilly) and as Novolin (Novo Nordisk). It is dispensed as either regular (R) or NPH (N) formulations. Five analogs of human insulin—three rapidly acting (insulin lispro, insulin aspart, insulin glulisine) and two long-acting (insulin glargine and insulin detemir)—have been approved by the FDA for clinical use (see below) (Table 27–10). Animal insulins are no longer available in the United States.

Table 27–10. Insulin preparations available in the United States.[1]
Rapidly acting human insulin analogs
Insulin lispro (Humalog, Lilly)
Insulin aspart (Novolog, Novo Nordisk)
Insulin glulisine (Apidra, Sanofi Aventis)
Short-acting regular insulin
Regular insulin (Lilly, Novo Nordisk)
Intermediate-acting insulins
NPH insulin (Lilly, Novo Nordisk)
Premixed insulins
70% NPH/30% regular (70/30 insulin - Lilly, Novo Nordisk)

50% NPH/50% regular (50/50 insulin - Lilly)
70% NPL/25% insulin lispro (Humalog Mix 75/25 - Lilly)
50% NPL/50% insulin lispro (Humalog Mix 50/50 - Lilly)
70% insulin aspart protamine/30% insulin aspart (Novolog Mix 70/30 - Novo Nordisk)
Long-acting human insulin analogs
Insulin glargine (Lantus, Sanofi Aventis)
Insulin detemir (Levemir, Novo Nordisk)

[1] All insulins available in the United States are recombinant human or human insulin analog origin. All the insulins are dispensed at U100 concentration. There is an additional U500 preparation of regular insulin.

NPH, neutral protamine Hagedorn.

Purity of insulin

"Purified" insulin is defined by FDA regulations as the degree of purity wherein proinsulin contamination is less than 10 ppm. All insulins presently available contain less than 10 ppm of proinsulin and are labeled as "purified." These purified insulins seem to preserve their potency quite well, so that refrigeration is recommended but not crucial. During travel, reserve supplies of insulin can thus be readily transported for weeks without losing potency if protected from extremes of heat or cold.

Concentration of insulin

At present, insulins in the United States are available in a concentration of 100 units/mL (U100), and all are dispensed in 10-mL vials. With the popularity of "low-dose" (0.5- or 0.3-mL) disposable insulin syringes, U100 can be measured with acceptable accuracy in doses as low as 1–2 units. For use in rare cases of severe insulin resistance in which large quantities of insulin are required, U500 regular human insulin (Humulin R) is available from Eli Lilly.

Insulin preparations

Insulins are classified into short-acting and long-acting insulin preparations. The short-acting preparations are regular insulin and the rapidly acting insulin analogs (Figure 27–1). They are dispensed as clear solutions at neutral pH and contain small amounts of zinc to improve their stability and shelf life. The long-acting preparations are NPH insulin and the long-acting insulin analogs. NPH insulin is dispensed as a turbid suspension at neutral pH with protamine in phosphate buffer. The long-acting insulin analogs are also dispensed as clear solutions; insulin glargine is at acidic pH and insulin detemir is at neutral pH. The Lente series of insulin (ultralente and lente) are no longer available in the United States. The rapidly acting insulin analogs and the long-acting insulins are designed for subcutaneous administration, while regular insulin can also be given intravenously. While insulin aspart has been approved for intravenous use (eg, in hyperglycemic emergencies), there is no advantage in using insulin aspart over regular insulin by this route.

Figure 27–1.

Extent and duration of action of various types of insulin–euglycemic hyperinsulinemic clamps in normal volunteers. A: Intermediate neutral protamine Hagedorn (NPH) insulin and long-acting insulin analogs. B: Regular insulin and rapidly acting insulin analogs.

Short-acting insulin preparations

Regular insulin

Regular insulin is a short-acting soluble crystalline zinc insulin whose effect appears within 30 minutes after subcutaneous injection and lasts 5–7 hours when usual quantities are administered. Intravenous infusions of regular insulin are particularly useful in the treatment of diabetic ketoacidosis and during the perioperative management of insulin-requiring diabetics. Regular insulin is indicated when the subcutaneous insulin requirement is changing rapidly, such as after surgery or during acute infections—although the rapidly acting insulin analogs may be preferable in these situations.

For markedly insulin-resistant persons who would otherwise require large volumes of insulin solution, a U500 preparation of human regular insulin is available. Since a U500 syringe is not available, a U100 insulin syringe or tuberculin syringe is used to measure doses. The physician should carefully note dosages in both units and volume to avoid overdosage.

Rapidly-acting insulin analogs

Insulin lispro (Humalog) is an insulin analog produced by recombinant technology, wherein two amino acids near the carboxyl terminal of the B chain have been reversed in position: Proline at position B28 has been moved to B29 and lysine has been moved from B29 to B28. Insulin aspart (Novolog) is a single substitution of proline by aspartic acid at position B28. Insulin glulisine (Apidra) differs from human insulin in that the amino acid asparagine at position B3 is replaced by lysine and the lysine in position B29 by glutamic acid. These changes result in these three analogs having less tendency to form hexamers, in contrast to human insulin. When injected subcutaneously, the analogs quickly dissociate into monomers and are absorbed very rapidly, reaching peak serum values in as soon as 1 hour—in contrast to regular human insulin, whose hexamers require considerably more time to dissociate and become absorbed. The amino acid changes in these analogs do not interfere with their binding to the insulin receptor, with the circulating half-life, or with their immunogenicity, which are all identical with those of human regular insulin.

Clinical trials have demonstrated that the optimal times of preprandial subcutaneous injection of comparable doses of the rapidly acting insulin analogs and of regular human insulin are 20 minutes and 60 minutes, respectively, before the meal. While this more rapid onset of action has been welcomed as a great convenience by diabetic patients who object to waiting as long as 60 minutes after injecting regular human insulin before they can begin their meal, patients must be taught to ingest adequate absorbable carbohydrate early in the meal to avoid hypoglycemia during the meal. Another desirable feature of insulin lispro is that its duration of action remains at about 4 hours irrespective of dosage. This contrasts with regular insulin, whose duration of action is prolonged when larger doses are used.

The rapidly acting analogs are also commonly used in pumps. In a double-blind crossover study comparing insulin lispro with regular insulin in insulin pumps, persons using insulin lispro had lower HbA_{1c} values and improved postprandial glucose control with the same frequency of hypoglycemia. The concern remains that in the event of pump failure, users of the rapidly acting insulin analogs will have more rapid onset of hyperglycemia and ketosis.

Long-acting insulin preparations

NPH (neutral protamine Hagedorn or isophane) insulin

NPH is an intermediate-acting insulin whose onset of action is delayed by combining 2 parts soluble crystalline zinc insulin with 1 part protamine zinc insulin. This produces equivalent amounts of insulin and protamine, so that neither is present in an uncomplexed form ("isophane").

Its onset of action is delayed to 2–4 hours, and its peak response is generally reached in about 8–10 hours. Because its duration of action is often less than 24 hours (with a range of 10–20 hours), most patients require at least two injections daily to maintain a sustained insulin effect. Occasional vials of NPH insulin have tended to show unusual clumping of their contents or "frosting" of the container, with considerable loss of bioactivity. This instability is rare and occurs less frequently if NPH human insulin is refrigerated when not in use and if bottles are discarded after 1 month of use.

Insulin glargine

Insulin glargine is an insulin analog in which the asparagine at position 21 of the A chain of the human insulin molecule is replaced by glycine and two arginines are added to the carboxyl terminal of the B chain. The arginines raise the isoelectric point of the molecule closer to neutral, making it more soluble in an acidic environment. In contrast, human insulin has an isoelectric point of pH 5.4. Insulin glargine is a clear insulin which, when injected into the neutral pH environment of the subcutaneous tissue, forms microprecipitates that slowly release the insulin into the circulation. It lasts for about 24 hours without any pronounced peaks and is given once a day to provide basal coverage. This insulin cannot be mixed with the other human insulins because of its acidic pH. When this insulin was given as a single injection at bedtime to type 1 patients, fasting hyperglycemia was better controlled when compared with bedtime NPH insulin. The clinical trials also suggest that there may be less nocturnal hypoglycemia with this insulin when compared with NPH insulin.

In one clinical trial involving type 2 patients, insulin glargine was associated with a slightly higher progression of retinopathy when compared with NPH insulin. The frequency was 7.5% with the analog and 2.7% with the NPH. This finding, however, was not seen in other clinical trials with this analog. Insulin glargine does have a sixfold greater affinity for IGF-1 receptor compared with the human insulin. There has also been a report that insulin glargine had increased mitogenicity compared with human insulin in a human osteosarcoma cell line. The significance of these observations is not yet clear. Because of lack of safety data, use of insulin glargine during pregnancy is not recommended.

Insulin detemir

Insulin detemir is an insulin analog in which the tyrosine at position 30 of the chain has been removed and a 14-C fatty acid chain (tetradecanoic acid) is attached to the lysine at position 29 by acylation. The fatty acid chain makes the molecule more lipophilic than native insulin and the addition of zinc stabilizes the molecule and leads to formation of hexamers. After injection, self-association at the injection site and albumin binding in the circulation via the fatty acid side chain, leads to slower distribution to peripheral target tissues and prolonged duration of action. The affinity of insulin detemir is fourfold to fivefold lower than that of human soluble insulin and therefore the U100 formulation of insulin detemir has an insulin concentration of 2400 nmol/mL compared with 600 nmol/mL for NPH. The duration of action for insulin detemir is about 17 hours at therapeutically relevant doses. It is recommended that the insulin be injected once or twice a day to achieve a stable basal coverage. This insulin has been reported to have lower within-subject pharmacodynamic variability compared with NPH insulin and insulin glargine. In vitro studies do not suggest any clinically relevant albumin binding interactions between insulin detemir and fatty acids or protein-bound drugs. Since there is a vast excess (~400,000) of albumin binding sites available in plasma per insulin detemir molecule, it is unlikely that hypoalbuminemic disease states will affect the ratio of bound to free insulin detemir.

Mixed insulin preparations

Since intermediate insulins require several hours to reach adequate therapeutic levels, their use in patients with type 1 diabetes requires supplements of regular or rapidly acting insulin analogs preprandially. For convenience, regular or rapidly acting insulin analogs and NPH insulin may be mixed together in the same syringe and injected subcutaneously in split dosage before breakfast and supper. It is recommended that the regular insulin or rapidly acting insulin analog be withdrawn first, then the NPH insulin and that the injection be given immediately after loading the syringe. Stable premixed insulins (70% NPH and 30% regular or 50% of each) are available as a convenience to patients who have difficulty mixing insulin because of visual problems or impairment of manual dexterity. Premixed preparations of insulin lispro and NPH insulins are unstable because of exchange of insulin lispro with the human insulin in the protamine complex. Consequently, the soluble component becomes over time a mixture of regular and insulin lispro at varying ratios. In an attempt to remedy this, an intermediate insulin composed of isophane complexes of protamine with insulin lispro was developed called NPL (neutral protamine lispro). This insulin has the same duration of action as NPH insulin. Premixed combinations of NPL and insulin lispro (eg, 75:25, 50:50, and 25:75 of NPL:insulin lispro) have been tested. Both 75% NPL/25% insulin lispro mixture (Humalog Mix 75/25) and 50% NPL/50% insulin lispro mixture (Humalog Mix 50/50) are available for clinical use. Similarly, a 70% insulin aspart protamine/30% insulin aspart (NovoLogMix 70/30) is available. The main advantages of these mixtures are that they can be given within 15 minutes of starting a meal and they are superior in controlling the postprandial glucose rise after a carbohydrate rich meal. These benefits have not translated into improvements in HbA_{1c} levels when compared with the usual 70% NPH/30% regular mixture.

The longer-acting insulin analogs cannot be mixed with either regular insulin or the rapidly acting insulin analogs.

Methods of insulin administration

Insulin syringes and needles

Plastic disposable syringes are available in 1-mL, 0.5-mL, and 0.3-mL sizes. The "low-dose" 0.3-mL syringes have become increasingly popular, because many diabetics do not take more than 30 units of insulin in a single injection except in rare instances of extreme insulin resistance. Two lengths of needles are available: short (8 mm) and long (12.7 mm). Long needles are preferable in obese patients to reduce variability of insulin absorption. Ultrafine needles as small as 31 gauge reduce the pain of injections. "Disposable" syringes may be reused until blunting of the needle occurs (usually after three to five injections). Sterility adequate to avoid infection with reuse appears to be maintained by recapping syringes between uses. Cleansing the needle with alcohol may not be desirable since it can dissolve the silicone coating and can increase the pain of skin puncturing.

Any part of the body covered by loose skin can be used, such as the abdomen, thighs, upper arms, flanks, and upper buttocks. Preparation with alcohol is no longer required prior to injection as long as the skin is clean. Rotation of sites continues to be recommended to avoid delayed absorption when fibrosis or lipohypertrophy occurs from repeated use of a single site. However, considerable variability of absorption rates from different sites, particularly with exercise, may contribute to the instability of glycemic control in certain type 1 patients if injection sites are rotated too frequently in different areas of the body. Consequently, it is best to limit injection sites to a single region of the body and rotate sites within that region. The abdomen is recommended for subcutaneous injections, since regular insulin has been shown to absorb more rapidly from there than from other subcutaneous sites. The effect of anatomic regions appears to be much less pronounced with the analog insulins.

Insulin pen injector devices

Insulin pens eliminate the need for carrying insulin vials and syringes. Cartridges of insulin lispro, insulin aspart, insulin detemir, insulin glargine, regular insulin, NPH insulin, and 70% NPH/30% regular insulin are available for reusable pens (Novo Nordisk, Becton Dickinson, and Sanofi Aventis pens). Disposable prefilled pens are also available for insulin lispro, insulin aspart, insulin detemir, insulin glargine, NPH, 70% NPH/30% regular, 75% NPL/25% insulin lispro, 50% NPL/50% insulin lispro, and 70% insulin aspart protamine/30% insulin aspart. Thirty-one gauge needles (5, 6, and 8 mm long) for these pens make injections almost painless.

Insulin pumps

In the United States, Medtronic Mini-Med, Animas, Deltec. Insulet, and Roche make insulin infusion pumps for subcutaneous delivery of insulin. These pumps are small (about the size of a pager) and very easy to program. They offer many features, including the ability to set a number of different basal rates throughout the 24 hours and to adjust the time over which bolus doses are given. They also are able to detect pressure build-up if the catheter is kinked. Improvements have also been made in the infusion sets. The catheter connecting the insulin reservoir to the subcutaneous cannula can be disconnected, allowing the patient to remove the pump temporarily (eg, for bathing). The great advantage of continuous subcutaneous insulin infusion (CSII) is that it allows for establishment of a basal profile tailored to the patient. The patient therefore is able to eat with less regard to timing because the basal insulin infusion should maintain constant blood glucose between meals. Also the ability to adjust the basal insulin infusion makes it easier for the patient to manage glycemic excursions that occur with exercise.

CSII therapy is appropriate for patients who are motivated, mechanically inclined, educated about diabetes (diet, insulin action, treatment of hypoglycemia and hyperglycemia), and willing to monitor their blood glucose four to six times a day. Known complications of CSII include ketoacidosis, which can occur when insulin delivery is interrupted, and skin infections. Another disadvantage is its cost and the time demanded of physicians and staff in initiating therapy.

Inhaled insulin

Exubera, the first inhaled insulin preparation approved by the FDA is no longer available; the manufacturer stopped marketing it because of lack of demand. In clinical trials, Exubera was as effective as subcutaneous regular insulin in controlling postprandial glucose excursions. Physicians, however, were reluctant to prescribe Exubera for a number of reasons, including a lack of long-term safety data on pulmonary function, awkward dosing schedule, availability of other insulin delivery systems, and cost and lack of insurance coverage.

Transplantation

Pancreas transplantation at the time of kidney transplantation is becoming more widely accepted. Patients undergoing simultaneous pancreas and kidney transplantation have an 85% chance of pancreatic graft survival and a 92% chance of kidney graft survival after 1 year. Solitary pancreatic transplantation in the absence of a need for kidney transplantation should be considered only in those rare patients who fail all other insulin therapeutic approaches and who have frequent severe hypoglycemia or who have life-threatening complications related to their lack of metabolic control.

Islet cell transplantation is a minimally invasive procedure, and investigators in Edmonton, Canada, have reported initial insulin independence in a small number of patients with type 1 diabetes who underwent this procedure. Using islets from multiple donors and corticosteroid-free immunosuppression, percutaneous transhepatic portal vein transplantation of islets was achieved in over 20 subjects. Although all of the initial cohort was able to achieve insulin independence posttransplantation (some for more than 2 years of follow-up), a decline in insulin secretion has occurred over time and the subjects have again required supplemental insulin. All patients had complete correction of severe hypoglycemic reactions, leading to a marked improvement in overall quality of life. Even if long-term insulin independence is demonstrated, wide application of this procedure for the treatment of type 1 diabetes is limited by the dependence on multiple donors and the requirement for potent long-term immunotherapy.

General Considerations in Treatment of Diabetes

Insulin-treated patients with diabetes can have a full and satisfying life. However, "free" diets and unrestricted activity are still not advised. Until new methods of insulin replacement are developed that provide more normal patterns of insulin delivery in response to metabolic demands, multiple feedings with carbohydrate counting will continue to be recommended, and certain occupations potentially hazardous to the patient or others will continue to be prohibited because of risks due to hypoglycemia. The American Diabetic Association can act as a patient advocate in case of employment questions.

Exercise increases the effectiveness of insulin, and moderate exercise is an excellent means of improving utilization of fat and carbohydrate in diabetic patients. A judicious balance of the size and frequency of meals with moderate regular exercise can often stabilize the insulin dosage in diabetics who tend to slip out of control easily. Strenuous exercise can precipitate hypoglycemia in an unprepared patient, and diabetics must therefore be taught to reduce their insulin dosage in anticipation of strenuous activity or to take supplemental carbohydrate. Injection of insulin into a site farthest away from the muscles most involved in exercise may help ameliorate exercise-induced hypoglycemia, since insulin injected in the proximity of exercising muscle may be more rapidly mobilized.

All diabetic patients must receive adequate instruction on personal hygiene, especially with regard to care of the feet, skin, and teeth. All infections (especially pyogenic ones) provoke the release of high levels of insulin antagonists such as catecholamines or glucagon and thus bring about a marked increase in insulin requirements. Supplemental regular insulin is often required to correct hyperglycemia during infection.

Steps in the Management of the Diabetic Patient

Diagnostic Examination

Any features of the clinical picture that suggest end-organ insensitivity to insulin, such as visceral obesity, must be identified. The family history should document not only the incidence of diabetes in other members of the family but also the age at onset, whether it was associated with obesity, and whether insulin was required. An attempt should be made to characterize the diabetes as type 1 or type 2, based on the clinical features present and on whether or not ketonuria accompanies the glycosuria. For the occasional patient, measurement of ICA, GAD65, IAA, and ICA 512 antibodies can help distinguish between type 1 and type 2 diabetes. Many patients in whom type 1 diabetes is newly diagnosed still have significant endogenous insulin production, and C peptide levels do not reliably distinguish between type 1 and type 2 diabetes. Other factors that increase cardiac risk, such as smoking history, presence of hypertension or hyperlipidemia, or oral contraceptive pill use, should be recorded.

Laboratory diagnosis should document fasting plasma glucose levels above 126 mg/dL or postprandial values consistently above 200 mg/dL and whether ketonuria accompanies the glycosuria. A glycohemoglobin measurement is useful for assessing the effectiveness of future therapy. Some flexibility of clinical judgment is appropriate when diagnosing diabetes mellitus in the elderly patient with borderline hyperglycemia.

Baseline values include fasting plasma triglycerides, total cholesterol and HDL-cholesterol, electrocardiography, kidney function studies, peripheral pulses, and neurologic, podiatric, and ophthalmologic examinations to help guide future assessments.

Patient Education (Self-Management Training)

Since diabetes is a lifelong disorder, education of the patient and the family is probably the most important obligation of the clinician who provides initial care. The best persons to manage a disease that is affected so markedly by daily fluctuations in environmental stress, exercise, diet, and infections are the patients themselves and their families. The "teaching curriculum" should include explanations by the physician or nurse of the nature of diabetes and its potential acute and chronic hazards and how they can be recognized early and prevented or treated. Self-monitoring of blood glucose should be emphasized, especially in insulin-requiring diabetic patients, and instructions must be given on proper testing and recording of data. Patients should be provided with algorithms they can use to adjust the timing and quantity of their insulin dose, food, and exercise in response to measured blood glucose values. The targets for blood glucose control should be elevated appropriately in elderly patients since they have the greatest risk if subjected to hypoglycemia and the least long-term benefit from more rigid glycemic control. Advice on personal hygiene, including detailed instructions on foot care, as well as individual instruction on diet and specific hypoglycemic therapy, should be provided. Patients should be told about community agencies, such as Diabetes Association chapters, that can serve as a continuing source of instruction. Finally, vigorous efforts should be made to persuade new diabetics who smoke to give up the habit, since large vessel peripheral vascular disease and debilitating retinopathy are less common in nonsmoking diabetic patients.

Therapy

Treatment must be individualized on the basis of the type of diabetes and specific needs of each patient. However, certain general principles of management can be outlined for hyperglycemic states of different types.

Type 2 diabetes

The obese patient with type 2 diabetes

The most common type of diabetic patient is obese, is non–insulin-dependent, and has hyperglycemia because of a combination of insulin resistance and beta cell failure.

Weight reduction

Treatment is directed toward achieving weight reduction, and prescribing a diet is only one means to this end. Behavior modification to achieve adherence to the diet—as well as increased physical activity to expend energy—is also required. Cure can be achieved by reducing adipose stores, with consequent restoration of tissue sensitivity to insulin, but weight reduction is hard to achieve and even more difficult to maintain with our current therapies. The presence of diabetes with its added risk factors may motivate the obese diabetic to greater efforts to lose weight. (See also Chapter 29: Nutritional Disorders.)

Hypoglycemic agents

If the patient is not able to achieve target glycemic control with weight management and exercise, then pharmacologic therapy is indicated. The choice of initial agent depends on a number of factors, including comorbid conditions, adverse reactions to the medications, ability of the patient to monitor for hypoglycemia, drug cost, and patient and physician preferences. **Metformin** is advantageous because apart from lowering glucose without the risk of hypoglycemia, it also lowers triglycerides and promotes some modest weight loss. The drug, however, cannot be used in patients with end-stage chronic kidney disease, and gastrointestinal side effects develop in some patients at even the lowest doses.

Thiazolidinediones improve peripheral insulin resistance and lower glucose without causing hypoglycemia. Both of the available thiazolidinediones, however, can cause fluid retention and are contraindicated in patients with heart failure. They also very commonly increase weight, which patients find distressing, affecting adherence. The drugs increase fracture risk in women further limiting their use. Pioglitazone is the preferred choice until there is more definitive data regarding rosiglitazone and the risk of ischemic heart disease. Both drugs are contraindicated in patients with active liver disease and in patients with liver enzymes 2.5 times the upper limit of normal.

Sulfonylureas have been available for many years and their use in combination with metformin is well established. They do, however, have the propensity of causing hypoglycemia and weight gain. The -**glucosidase inhibitors** have modest glucose lowering effects and have gastrointestinal side effects. **Exenatide** has a lower risk of hypoglycemia than the sulfonylureas and promotes weight loss. However, it needs to be given by injection, causes nausea, may cause pancreatitis, and is contraindicated in patients with gastroparesis. **Sitagliptin** also has a low risk of hypoglycemia, and it does not cause nausea or vomiting. It can also be used in patients with kidney impairment. There are, however, reports of serious allergic reactions, including anaphylaxis, angioedema, and Stevens-Johnson syndrome.

For most obese patients with mild type 2 diabetes, metformin is the first-line agent. If it proves to be inadequate, then a second agent should be added. In those patients where the problem is hyperglycemia after a carbohydrate rich meal (such as dinner), then a short-acting secretagogue before meals may suffice to get the glucose levels into the target range. Patients with severe insulin resistance may be candidates for pioglitazone. Subjects who are very concerned about weight gain may benefit from a trial of exenatide. If two agents are inadequate, then a third agent is added, although data regarding efficacy of such combined therapy are limited. Experienced clinicians have found that instead of maximizing the dose of each agent before adding another agent, some patients are more tolerant of submaximal combinations of drugs. Insulin therapy should be instituted if combination of oral agents (and exenatide) fail to restore euglycemia or if there are concerns about side effects. Weight-reducing interventions should continue and may allow for simplification of this regimen in the future.

When the combination of oral agents (and exenatide) fail to achieve euglycemia in patients with type 2 diabetes, various insulin regimens may be effective. One proposed regimen is to continue the oral combination therapy and then simply add a bedtime dose of NPH or long-acting insulin analog (insulin glargine or insulin detemir) to reduce excessive nocturnal hepatic glucose output and improve fasting glucose levels. If the patient does not achieve target glucose levels during the day, then daytime insulin treatment can be initiated. A convenient insulin regimen under these circumstances is a split dose of 70/30 NPH/regular mixture (or Humalog Mix 75/25 or NovoLogMix 70/30) before breakfast and before dinner. If this regimen fails to achieve satisfactory glycemic goals or is associated with unacceptable frequency of hypoglycemic episodes, then a more intensive regimen of multiple insulin injections can be instituted as in patients with type 1 diabetes. Metformin principally reduces hepatic glucose output and pioglitazone improves peripheral insulin resistance, so it is a reasonable option to continue these drugs when insulin therapy is instituted. The sulfonylureas also have been shown to be of continued benefit. Thus, the continued use of the oral drugs may permit the use of lower doses of insulin and simpler regimens. There is no data on the continued administration of exenatide under these circumstances.

The nonobese patient with type 2 diabetes

Nonobese patients with type 2 diabetes frequently have increased visceral adiposity—the so-called metabolically obese normal weight patient—and the treatment algorithm is much the same as in the obese patient except there is not as much emphasis on weight loss. However, exercise remains an important aspect of treatment. Persons who do not have central obesity or insulin resistance should be evaluated for other types of diabetes such as LADA or MODY. Patients with LADA can initially be treated with oral agents but require insulin within a few years, so experienced clinicians often prescribe insulin for these patients when the diagnosis is made.

Type 1 diabetes

Traditional once- or twice-daily insulin regimens are usually ineffective in type 1 patients without residual endogenous insulin. In these patients, information and counseling based on the findings of the DCCT (see above) should be provided about the advantages of taking multiple injections of insulin in conjunction with self-blood glucose monitoring. If near-normalization of blood glucose is attempted, at least four measurements of capillary blood glucose and three or four insulin injections are necessary.

A combination of rapidly acting insulin analogs and long-acting insulin analogs allows for more physiologic insulin replacement. The rapidly acting insulin analogs have been advocated as a safer and much more convenient alternative to regular human insulin for preprandial use. In a study comparing regular insulin with insulin lispro, daily insulin doses and hemoglobin A_{1c} levels were similar, but insulin lispro improved postprandial control, reduced hypoglycemic episodes, and improved patient convenience compared with regular insulin. However, because of their relatively short duration (no more than 3–4 hours), the rapidly acting insulin analogs need to be combined with longer-acting insulins to provide basal coverage and avoid hyperglycemia prior to the next meal. In addition to carbohydrate content of the meal, the effect of simultaneous fat ingestion must also be considered a factor in determining the rapidly acting insulin analog dosage required to control the glycemic increment during and just after the meal. With low-carbohydrate content and high-fat intake, there is an increased risk of hypoglycemia from insulin lispro within 2 hours after the meal. Table 27–11 illustrates a regimen with a rapidly acting insulin analog and insulin detemir or insulin glargine that might be appropriate for a 70-kg person with type 1 diabetes eating meals providing standard carbohydrate intake and moderate to low fat content.

Table 27–11. Examples of intensive insulin regimens using rapidly acting insulin analogs (insulin lispro, aspart, or glulisine) and insulin detemir, or insulin glargine in a 70-kg man with type 1 diabetes.[1–3]

	Pre-Breakfast	**Pre-Lunch**	**Pre-Dinner**	**At Bedtime**
Rapidly acting	5 units	4 units	6 units	—

insulin analog				
Insulin detemir	6–7 units			8–9 units
		OR		
Rapidly acting insulin analog	5 units	4 units	6 units	—
Insulin glargine	—	—	—	15–16 units

[1] Assumes that patient is consuming approximately 75 g carbohydrate at breakfast, 60 g at lunch, and 90 g at dinner.

[2] The dose of rapidly acting insulin can be raised by 1 or 2 units if extra carbohydrate (15–30 g) is ingested or if premeal blood glucose is > 170 mg/dL.

[3] Insulin glargine or insulin detemir must be given as a separate injection.

Insulin glargine is usually given once in the evening to provide 24-hour coverage. This insulin *cannot be mixed* with any of the other insulins and must be given as a separate injection. There are occasional patients in whom insulin glargine does not seem to last for 24 hours, and in such cases it needs to be given twice a day. As shown, insulin detemir may also need to be given twice a day to get adequate 24-hour basal coverage. Alternatively, small doses of NPH (~ 3 to 4 units) can be given with each meal to provide daytime basal coverage with a larger dose at night. Unlike the long-acting insulin analogs, NPH can be mixed in the same syringe as the insulin lispro, insulin aspart, and insulin glulisine.

Continuous subcutaneous insulin infusion (CSII) by portable battery-operated "open loop" devices currently provides the most flexible approach, allowing the setting of different basal rates throughout the 24 hours and permitting patients to delay or skip meals and vary meal size and composition. The dosage is usually based on providing 50% of the estimated insulin dose as basal and the remainder as intermittent boluses prior to meals. For example, a 70-kg man requiring 35 units of insulin per day may require a basal rate of 0.7 units per hour throughout the 24 hours with the exception of 3 AM to 8 AM, when 0.8 units per hour might be appropriate (for the dawn phenomenon). The meal bolus would depend on the carbohydrate content of the meal and the premeal blood glucose value. One unit per 15 g of carbohydrate plus 1 unit for 50 mg/dL of blood glucose above a target value (eg, 120 mg/dL) is a common starting point. Further adjustments to basal and bolus dosages would depend on the results of blood glucose monitoring. The majority of patients use the rapidly acting insulin analogs in the pumps. One of the more difficult therapeutic problems in managing patients with type 1 diabetes is determining the proper adjustment of insulin dose when the prebreakfast blood glucose level is high. Occasionally, the prebreakfast hyperglycemia is due to the Somogyi effect, in which nocturnal hypoglycemia leads to a surge of counterregulatory hormones to produce high blood glucose levels by 7 AM. However, a more common cause for prebreakfast hyperglycemia is the waning of circulating insulin levels by the morning. Also, the "dawn phenomenon"—reduced tissue sensitivity to insulin between 5 AM and 8 AM—is present in as many as 75% of type 1 patients and can aggravate the hyperglycemia.

Table 27–12 shows that diagnosis of the cause of prebreakfast hyperglycemia can be facilitated by self-monitoring of blood glucose at 3 AM in addition to the usual bedtime and 7 AM measurements. This is required for only a few nights, and when a particular pattern emerges from monitoring blood glucose levels overnight, appropriate therapeutic measures can be taken. The Somogyi effect can be treated by eliminating the dose of intermediate insulin at dinnertime and giving it at a lower dosage at bedtime or by supplying more food at bedtime. When a waning insulin level is the cause, then either increasing the evening dose or shifting it from dinnertime to bedtime (or both) can be effective. A bedtime dose either of insulin glargine or insulin detemir provides more sustained overnight insulin levels than human NPH and may be effective in managing refractory prebreakfast hyperglycemia. If this fails, insulin pump therapy may be required. When the dawn phenomenon alone is present, the dosage of intermediate insulin can be divided between dinnertime and bedtime; when insulin pumps are used, the basal infusion rate can be increased (eg, from 0.8 unit/h to 0.9 unit/h from 6 AM until breakfast).

Table 27–12. Prebreakfast hyperglycemia: Classification by blood glucose and insulin levels.

	Blood Glucose (mg/dL)			**Free Immunoreactive Insulin (microunit/mL)**		
	10:00 PM	**3:00 AM**	**7:00 AM**	**10:00 PM**	**3:00 AM**	**7:00 AM**
Somogyi effect	90	40	200	High	Slightly high	Normal
Dawn phenomenon	110	110	150	Normal	Normal	Normal
Waning of insulin dose plus dawn phenomenon	110	190	220	Normal	Low	Low
Waning of insulin dose plus dawn phenomenon	110	40	380	High	Normal	Low

plus Somogyi effect						

Acceptable Levels of Glycemic Control

A reasonable aim of therapy is to approach normal glycemic excursions without provoking severe or frequent hypoglycemia. What has been considered "acceptable" control includes blood glucose levels of 90–130 mg/dL before meals and after an overnight fast, and levels no higher than 180 mg/dL 1 hour after meals and 150 mg/dL 2 hours after meals. Glycohemoglobin levels should be no higher than 1% above the upper limit of the normal range for any particular laboratory. It should be emphasized that the value of blood pressure control was as great as or greater than glycemic control in type 2 patients as regards microvascular as well as macrovascular complications.

Complications of Insulin Therapy

Hypoglycemia

When the blood glucose falls to around 54 mg/dL, the patient starts to experience both sympathetic (tachycardia, palpitations, sweating, tremulousness) and parasympathetic (nausea, hunger) nervous system symptoms. If these autonomic symptoms are ignored and the glucose levels fall further (to around 50 mg/dL), then neuroglycopenic symptoms appear, including irritability, confusion, blurred vision, tiredness, headache, and difficulty speaking. A further decline in glucose can then lead to loss of consciousness or even a seizure. With repeated episodes of hypoglycemia, there is adaptation, and autonomic symptoms do not occur until the blood glucose levels are much lower and so the first symptoms are often due to neuroglycopenia. This condition is referred to as "hypoglycemic unawareness." It has been shown that hypoglycemic unawareness can be reversed by keeping glucose levels high for a period of several weeks. Except for sweating, most of the sympathetic symptoms of hypoglycemia are blunted in patients receiving -blocking agents for angina pectoris or hypertension. Though not absolutely contraindicated, these drugs must be used with caution in insulin-requiring diabetics, and $_1$-selective blocking agents are preferred.

Hypoglycemia in insulin-treated patients with diabetes occurs as a consequence of three factors: behavioral issues, impaired counterregulatory systems, and complications of diabetes.

Behavioral issues include injecting too much insulin for the amount of carbohydrates ingested. Drinking alcohol in excess, especially on an empty stomach, can also cause hypoglycemia. In patients with type 1 diabetes, hypoglycemia can occur during or even several hours after exercise, and so glucose levels need to be monitored and food and insulin adjusted. Some patients do not like their glucose levels to be high, and they treat every high glucose level aggressively. These individuals who "stack" their insulin—that is, give another dose of insulin before the first injection has had its full action—can develop hypoglycemia.

Counterregulatory issues resulting in hypoglycemia include impaired glucagon response, sympatho-adrenal responses, and cortisol deficiency. Patients with diabetes of greater than 5 years duration lose their glucagon response to hypoglycemia. As a result, they are at a significant disadvantage in protecting themselves against falling glucose levels. Once the glucagon response is lost, their sympatho-adrenal responses take on added importance. Unfortunately, aging, autonomic neuropathy, or hypoglycemic unawareness due to repeated low glucose levels further blunts the sympatho-adrenal responses. Occasionally, Addison disease develops in persons with type 1 diabetes mellitus; when this happens, insulin requirements fall significantly, and unless insulin dose is reduced, recurrent hypoglycemia will develop.

Complications of diabetes that increase the risk for hypoglycemia include autonomic neuropathy, gastroparesis, and end-stage chronic kidney disease. The sympathetic nervous system is an important system alerting the individual that the glucose level is falling by causing symptoms of tachycardia, palpitations, sweating, and tremulousness. Failure of the sympatho-adrenal responses increases the risk of hypoglycemia. In addition, in patients with gastroparesis, if insulin is given before a meal, the peak of insulin action may occur before the food is absorbed causing the glucose levels to fall. Finally, in end-stage chronic kidney disease, hypoglycemia can occur presumably because of decreased insulin clearance as well as loss of renal contribution to gluconeogenesis in the postabsorptive state.

To prevent and treat insulin-induced hypoglycemia, the diabetic patient should carry glucose tablets or juice at all times. For most episodes, ingestion of 15 grams of carbohydrate is sufficient to reverse the hypoglycemia. The patient should be instructed to check the blood glucose in 15 minutes and treat again if the glucose level is still low. A parenteral glucagon emergency kit (1 mg) should be provided to every patient with diabetes who is receiving insulin therapy. Family or friends should be instructed how to inject it subcutaneously or intramuscularly into the buttock, arm, or thigh in the event that the patient is unconscious or refuses food. The drug can occasionally cause vomiting, and the unconscious patient should be turned on his or her side to protect the airway. The glucagon mobilizes glycogen from the liver, raising the blood glucose by about 36 mg/dL in about 15 minutes. After the patient recovers consciousness, additional oral carbohydrate should be given. People with diabetes receiving hypoglycemic drug therapy should also wear an identification MedicAlert bracelet or necklace or carry a card in his or her wallet. The telephone number for the MedicAlert Foundation International in Turlock, California, is 1-800-ID-ALERT and the Internet address is www.medicalert.org.

Medical personnel treating severe hypoglycemia can give 50 mL of 50% glucose solution by rapid intravenous infusion. If intravenous therapy is not available, 1 mg of glucagon can be injected intramuscularly. If the patient is stuporous and glucagon is not available, small amounts of honey or syrup or glucose gel (15 g) can be inserted within the buccal pouch, but, in general, oral feeding is contraindicated in unconscious patients. Rectal administration of syrup or honey (30 mL per 500 mL of warm water) has been effective.

Immunopathology of Insulin Therapy

At least five molecular classes of insulin antibodies are produced during the course of insulin therapy in diabetes, including IgA, IgD, IgE, IgG, and IgM. With the increased therapeutic use of purified pork and especially human insulin, the various immunopathologic syndromes such as insulin allergy, immune insulin resistance, and lipoatrophy have become quite rare since the titers and avidity of these induced antibodies are generally quite low.

Insulin allergy

Insulin allergy, or immediate-type hypersensitivity, is a rare condition in which local or systemic urticaria is due to histamine release from tissue mast cells sensitized by adherence of anti-insulin IgE antibodies. In severe cases, anaphylaxis results. When only human insulin has been used from the onset of insulin therapy, insulin allergy is exceedingly rare. Antihistamines, corticosteroids, and even desensitization may be required, especially for systemic hypersensitivity. There have been case reports of successful use of insulin lispro in those rare patients who have a generalized allergy to human insulin or insulin resistance due to a high titer of insulin antibodies.

Immune insulin resistance

Most insulin-treated patients develop a low titer of circulating IgG anti-insulin antibodies that neutralize to a small extent the action of insulin. With the old animal insulins, a high titer of circulating antibodies sometimes developed, resulting in extremely high insulin requirements—often more than 200 units daily. This is now rarely seen with the switch to highly purified pork or human insulins and has not been reported with the analogs.

Lipodystrophy at Injection Sites

Atrophy of subcutaneous fatty tissue leading to disfiguring excavations and depressed areas may rarely occur at the site of injection (see photograph). This complication results from an immune reaction, and it has become rarer with the development of pure and human insulin preparations. Lipohypertrophy, on the other hand, is a consequence of the pharmacologic effects of insulin being deposited in the same location repeatedly (see photograph). It can occur with purified insulins as well. Rotation of injection sites will prevent lipohypertrophy. There is a case report of a patient who had intractable lipohypertrophy with human insulin but no longer had the problem when he switched to insulin lispro.

Chronic Complications of Diabetes

Late clinical manifestations of diabetes mellitus include a number of pathologic changes that involve small and large blood vessels, cranial and peripheral nerves, the skin, and the lens of the eye. These lesions lead to hypertension, end-stage chronic kidney disease, blindness, autonomic and peripheral neuropathy, amputations of the lower extremities, myocardial infarction, and cerebrovascular accidents. These late manifestations correlate with the duration of the diabetic state subsequent to the onset of puberty. In type 1 diabetes, end-stage chronic kidney disease develops in up to 40% of patients, compared with less than 20% of patients with type 2 diabetes. As regards proliferative retinopathy, it ultimately develops in both types of diabetes but has a slightly higher prevalence in type 1 patients (25% after 15 years' duration). In patients with type 1 diabetes, complications from end-stage chronic kidney disease are a major cause of death, whereas patients with type 2 diabetes are more likely to have macrovascular diseases leading to myocardial infarction and stroke as the main causes of death. Cigarette use adds significantly to the risk of both microvascular and macrovascular complications in diabetic patients.

Ocular Complications

Diabetic cataracts

Premature cataracts occur in diabetic patients and seem to correlate with both the duration of diabetes and the severity of chronic hyperglycemia. Nonenzymatic glycosylation of lens protein is twice as high in diabetic patients as in age-matched nondiabetic persons and may contribute to the premature occurrence of cataracts.

Diabetic retinopathy

Three main categories exist: background, or "simple," retinopathy, consisting of microaneurysms, hemorrhages, exudates, and retinal edema; preproliferative retinopathy with arteriolar ischemia manifested as cotton-wool spots (small infarcted areas of retina); and proliferative, or "malignant," retinopathy, consisting of newly formed vessels (see photograph); (see funduscopy). Proliferative retinopathy is a leading cause of blindness in the United States, particularly since it increases the risk of retinal detachment. Vision-threatening retinopathy virtually never appears in type 1 patients in the first 3–5 years of diabetes or before puberty. Up to 20% of patients with type 2 diabetes have retinopathy at the time of diagnosis. Annual consultation with an ophthalmologist should be arranged for patients who have had type 1 diabetes for more than 3–5 years and for all patients with type 2 diabetes, because many were probably diabetic for an extensive period of time before diagnosis. Patients with any macular edema, severe nonproliferative retinopathy, or any proliferative retinopathy require the care of an ophthalmologist. Extensive "scatter" xenon or argon photocoagulation and focal treatment of new vessels reduce severe visual loss in those cases in which proliferative retinopathy is associated with recent vitreous hemorrhages or in which extensive new vessels are located on or near the optic disk. Macular edema, which is more common than proliferative retinopathy in patients with type 2 diabetes (up to 20% prevalence), has a guarded prognosis, but it has also responded to scatter therapy with improvement in visual acuity if detected early. Injection of bevacizumab (Avastin), an anti-vascular endothelial growth factor (anti-VEGF), into the eye has been shown to stop the growth of the new blood vessels in diabetic eye disease. Avoiding tobacco use and correction of associated hypertension are important therapeutic measures in the management of diabetic retinopathy. There is no contraindication to using aspirin in patients with proliferative retinopathy.

Glaucoma

Glaucoma occurs in approximately 6% of persons with diabetes. It is responsive to the usual therapy for open-angle disease. Neovascularization of the iris in diabetics can predispose to closed-angle glaucoma, but this is relatively uncommon except after cataract extraction, when growth of new vessels has been known to progress rapidly, involving the angle of the iris and obstructing outflow.

Diabetic Nephropathy

As many as 4000 cases of end-stage chronic kidney disease occur each year among diabetic people in the United States (see illustration). This is about one-third of all patients being treated for end-stage chronic kidney disease and represents a considerable national health expense.

Fig.

Development of renal failure in type 1 diabetes. (Reproduced, with permission, from Omachi R: The pathogenesis and prevention of diabetic nephropathy. West J Med 1986;145:222.)

The cumulative incidence of nephropathy differs between the two major types of diabetes. Patients with type 1 diabetes have a 30–40% chance of having nephropathy after 20 years—in contrast to the much lower frequency in type 2 diabetes patients, in whom only about 15–20% develop clinical kidney disease. However, since there are many more individuals affected with type 2 diabetes, end-stage chronic kidney disease is much more prevalent in type 2 than in type 1 diabetes in the United States and especially throughout the rest of the world. Improved glycemic control and more effective therapeutic measures to correct hypertension—and with the beneficial effects of ACE inhibitors—can reduce the development of end-stage chronic kidney disease among diabetics.

Diabetic nephropathy is initially manifested by proteinuria; subsequently, as kidney function declines, urea and creatinine accumulate in the blood.

Microalbuminuria

Sensitive radioimmunoassay methods of detecting small amounts of urinary albumin have permitted detection of microgram concentrations—in contrast to the less sensitive dipstick strips, whose minimal detection limit is 0.3–0.5%. Conventional 24-hour urine collections, in addition to being inconvenient for patients, also show wide variability of albumin excretion, since several factors such as sustained erect posture, dietary protein, and exercise tend to increase albumin excretion rates. For these reasons, a timed overnight urine collection or albumin-creatinine ratio in an early morning spot urine collected upon awakening is preferable. Normal subjects excrete less than 15 mcg/min during overnight urine collections; values of 20 mcg/min or higher are considered to represent abnormal microalbuminuria. In the early morning spot urine, a ratio of albumin (mcg/L) to creatinine (mg/L) of < 30 mcg/mg creatinine is normal, and a ratio of 30–300 mcg/mg creatinine suggests abnormal microalbuminuria. At least two of three timed overnight or early morning spot urine collections over a 3- to 6-month period should be abnormal before a diagnosis of microalbuminuria is justified.

Subsequent end-stage chronic kidney disease can be predicted by persistent urinary albumin excretion rates exceeding 30 mcg/min. Increased microalbuminuria correlates with increased levels of blood pressure and increased LDL cholesterol, and this may explain why increased proteinuria in diabetic patients is associated with an increase in cardiovascular deaths even in the absence of end-stage chronic kidney disease. Glycemic control as well as a low-protein diet (0.8 g/kg/d) may reduce both the hyperfiltration and the elevated microalbuminuria in patients in the early stages of diabetes and those with incipient diabetic nephropathy. Antihypertensive therapy also decreases microalbuminuria. Evidence from some studies—but not the UKPDS—supports a specific role for ACE inhibitors in reducing intraglomerular pressure in addition to their lowering of systemic hypertension. An ACE inhibitor (captopril, 50 mg twice daily) in normotensive diabetics impedes progression to proteinuria and prevents the increase in albumin excretion rate. Since microalbuminuria has been shown to correlate with elevated *nocturnal* systolic blood pressure, it is possible that "normotensive" diabetic patients with microalbuminuria have slightly elevated systolic blood pressure during sleep, which is lowered during antihypertensive therapy. This action may contribute to the reported efficacy of ACE inhibitor drugs in reducing microalbuminuria in "normotensive" patients.

Progressive diabetic nephropathy

Progressive diabetic nephropathy consists of proteinuria of varying severity occasionally leading to nephrotic syndrome with hypoalbuminemia, edema, and an increase in circulating LDL cholesterol as well as progressive azotemia. In contrast to all other kidney disorders, the proteinuria associated with diabetic nephropathy does not diminish with progressive end-stage chronic kidney disease (patients continue to excrete 10–11 g daily as creatinine clearance diminishes). As end-stage chronic kidney disease progresses, there is an elevation in the renal threshold at which glycosuria appears.

Hypertension develops with progressive kidney involvement, and coronary and cerebral atherosclerosis seems to be accelerated. Approximately two-thirds of adult patients with diabetes have hypertension. Once diabetic nephropathy has progressed to the stage of hypertension, proteinuria, or early chronic kidney disease, glycemic control is not beneficial in influencing its course. In this circumstance, antihypertensive medications, including ACE inhibitors, and restriction of dietary protein to 0.8 g/kg body weight per day are recommended. ACE inhibitors have been shown to protect against deterioration in kidney function in type 1 diabetic patients with clinical nephropathy. This beneficial effect appears to be due to improved glomerular hemodynamics that cannot be explained only by the antihypertensive action of these drugs. Captopril (25 mg three times daily) has shown a 50% reduction in the risk of the combined end points of death, dialysis, and transplantation in type 1 subjects with diabetic nephropathy and clinical proteinuria. During initiation of ACE inhibitor therapy, an increment in serum creatinine greater than 2 mg/dL due to a rapid fall in intraglomerular pressure—or the occurrence of persistent hyperkalemia (above 6 mEq/L) due to hyporeninemic hypoaldosteronism—is an indication to stop this medication.

Dialysis has been of limited value in the long-term treatment of chronic kidney disease due to diabetic nephropathy. At present, experience in kidney transplantation—especially from related donors—is more promising and is the treatment of choice in cases where there are no contraindications such as severe cardiovascular disease.

Diabetic Neuropathy

Diabetic neuropathies are the most common complications of diabetes affecting up to 50% of older patients with type 2 diabetes.

Peripheral neuropathy

Distal symmetric polyneuropathy

This is the most common form of diabetic peripheral neuropathy where loss of function appears in a stocking-glove pattern and is due to an axonal neuropathic process (see photograph). Longer nerves are especially vulnerable, hence the impact on the foot (see photograph). Both motor and sensory nerve conduction is delayed in the peripheral nerves, and ankle jerks may be absent.

Sensory involvement usually occurs first and is generally bilateral, symmetric, and associated with dulled perception of vibration, pain, and temperature. The pain can range from mild discomfort to severe incapacitating symptoms (see below). The sensory deficit may eventually be of sufficient degree to prevent patients from feeling pain. Patients who have a sensory neuropathy should therefore be examined with a 5.07 Semmes Weinstein filament and those who cannot feel the filament must be considered at risk for unperceived neuropathic injury.

The denervation of the small muscles of the foot result in clawing of the toes and displacement of the submetatarsal fat pads anteriorly. These changes, together with the joint and connective tissue changes, alter the biomechanics of the foot and increase plantar pressures. This combination of decreased pain threshold, abnormally high foot pressures, and repetitive stress (such as from walking) can lead to calluses and ulcerations in the high-pressure areas such as over the metatarsal heads (Plate 92). Peripheral neuropathy, autonomic neuropathy, and trauma also predisposes to the development of Charcot arthropathy. An acute case of Charcot foot arthropathy presents with pain and swelling, and if left untreated, leads to a "rocker bottom" deformity and ulceration. The early radiologic changes show joint subluxation and periarticular fractures. As the process progresses, there is frank osteoclastic destruction leading to deranged and unstable joints particularly in the midfoot. Not surprisingly, the key issue for the healing of neuropathic ulcers in a foot with good vascular supply is mechanical unloading. In addition, any infection should be treated with debridement and appropriate antibiotics; healing duration of 8–10 weeks is typical. Occasionally, when healing appears refractory, **platelet-derived growth factor** (becaplermin [Regranex]) should be considered for local application. A post-marketing epidemiologic study showed increased cancer deaths in patients who had used three or more tubes of becaplermin on their leg or feet ulcers, and there is now a "black box" warning on the drug label. Once ulcers are healed, therapeutic footwear is key to preventing recurrences. Custom molded shoes are reserved for patients with significant foot deformities. Other patients with neuropathy may require accommodative insoles that distribute the load over as wide an area as possible. Patients with foot deformities and loss of their protective threshold should get regular care from a podiatrist. Patients should be educated on appropriate footwear and those with loss of their protective threshold should be instructed to inspect their feet daily for reddened areas, blisters, abrasions, or lacerations.

Neuropathic ulcer under the head of the third metatarsal on the foot of a diabetic patient (courtesy of Javier La Fontaine, DPM; Used, with permission, from Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H, Tysinger J. *The Color Atlas of Family Medicine*. McGraw-Hill, 2009.)

Fig.

Distal symmetric polyneuropathy. Although interosseous muscle wasting often occurs more typically in the feet than in the hands, it is often more dramatic and more evident to the clinician when it occurs in the hands. Although the condition is usually an asymptomatic sign of diabetic neuropathy, the weakness that results from muscle wasting may impair the patient's ability to hold onto objects and may cause motor impairment. (Courtesy of Upjohn Co. Teaching Slides, Scope R Publications.)

Fig.

Neuropathic plantar ulcers. (Courtesy of Upjohn Co. Teaching Slides, Scope R Publications.)

Isolated peripheral neuropathy

Involvement of the distribution of only one nerve ("mononeuropathy") or of several nerves ("mononeuropathy multiplex") is characterized by sudden onset with subsequent recovery of all or most of the function. This neuropathology has been attributed to vascular ischemia or traumatic damage. Cranial and femoral nerves are commonly involved, and motor abnormalities predominate. The patient with cranial nerve involvement usually has diplopia and single third, fourth, or sixth nerve weakness on examination but the pupil is spared. A full recovery of function occurs in 6–12 weeks. Diabetic amyotrophy presents with onset of severe pain in the front of the thigh. Within a few days or weeks of the onset of pain, weakness and wasting of the quadriceps develops. As the weakness appears, the pain tends to improve. Management includes analgesia and improved diabetes control. The symptoms improve over 6–18 months.

Painful diabetic neuropathy

Hypersensitivity to light touch and occasionally severe "burning" pain, particularly at night, can become physically and emotionally disabling. Amitriptyline, 25–75 mg at bedtime, has been recommended for pain associated with diabetic neuropathy. Dramatic relief has often resulted within 48–72 hours. This rapid response is in contrast to the 2 or 3 weeks required for an antidepressive effect. Patients often attribute the benefit to their having a full night's sleep. Mild to moderate morning drowsiness is a side effect that generally improves with time or can be lessened by giving the medication several hours before bedtime. This drug should not be continued if improvement has not occurred after 5 days of therapy. If amitriptyline's anticholinergic effects are too troublesome, then nortriptyline can be used. Desipramine in doses of 25–150 mg/d seems to have the same efficacy as amitriptyline. Tricyclic antidepressants, in combination with the phenothiazine, fluphenazine, have been shown in two studies to be efficacious in painful neuropathy, with benefits unrelated to relief of depression. Gabapentin (900–1800 mg/d in three divided doses) has also been shown to be effective in the treatment of painful neuropathy and should be tried if the tricyclic drugs prove ineffective. Pregabalin, a congener of gabapentin, has been shown in an 8-week study to be more effective than placebo in treating painful diabetic peripheral neuropathy. However, this drug was not compared with an active control. Also, because of its abuse potential, it has been categorized as a schedule V controlled substance. Duloxetine, a serotonin and norepinephrine reuptake inhibitor, has been approved for the treatment of painful diabetic neuropathy. In clinical trials, this drug reduced the pain sensitivity score by 40–50%. Capsaicin, a topical irritant, has been found to be effective in reducing local nerve pain; it is dispensed as a cream (Zostrix 0.025%, Zostrix-HP 0.075%) to be rubbed into the skin over the painful region two to four times daily. Gloves should be used for application since hand contamination could result in discomfort if the cream comes in contact with eyes or sensitive areas such as the genitalia.

Diabetic neuropathic cachexia is a syndrome characterized by a symmetric peripheral neuropathy associated with profound weight loss (up to 60% of total body weight) and painful dysesthesias affecting the proximal lower limbs, the hands, or the lower trunk. Treatment is usually with insulin and analgesics. The prognosis is generally good, and patients typically recover their baseline weight with resolution of the painful sensory symptoms within 1 year.

Autonomic neuropathy

With autonomic neuropathy, there is evidence of postural hypotension, decreased cardiovascular response to the Valsalva maneuver, gastroparesis, alternating bouts of diarrhea (particularly nocturnal) and constipation, inability to empty the bladder, and impotence. Gastroparesis should be considered in type 1 diabetic patients in whom unexpected fluctuations and variability in their blood glucose levels develops after meals. Impotence due to neuropathy differs from psychogenic impotence in that the latter may be intermittent (erections occur under special circumstances), whereas diabetic impotence is usually persistent; aortoiliac occlusive disease may contribute to this problem.

Management of autonomic neuropathy

There is no consistently effective treatment for diabetic autonomic neuropathy. Metoclopramide has been of some help in treating diabetic gastroparesis over the short term, but its effectiveness seems to diminish over time. It is a dopamine antagonist that has central antiemetic effects as well as a cholinergic action to facilitate gastric emptying. It is given in a dose of 10 mg orally three or four times a day, 30 minutes before meals and at bedtime. Drowsiness, restlessness, fatigue, and lassitude are common adverse effects. Tardive dyskinesia and extrapyramidal effects also occur. Erythromycin appears to bind to motilin receptors in the stomach and has been found to improve gastric emptying in doses of 250 mg three times daily. Tegaserod (Zelnorm), the partial 5-HT4 agonist, has been withdrawn from the US market by the FDA, so it is no longer used for this indication. In selected patients, injections of botulinum toxin into the pylorus can reduce pylorus sphincter resistance and enhance gastric emptying. Gastric electrical stimulation has been reported to improve symptoms and quality of life indices in patients with gastroparesis refractory to pharmacologic therapy. Diarrhea associated with autonomic neuropathy has occasionally responded to broad-spectrum antibiotic therapy, although it often undergoes spontaneous remission. Refractory diabetic diarrhea is often associated with impaired sphincter control and fecal incontinence. Therapy with loperamide, 4–8 mg daily, or diphenoxylate with atropine, two tablets up to four times a day, may provide relief. In more severe cases, tincture of paregoric or codeine (60-mg tablets) may be required to reduce the frequency of diarrhea and improve the consistency of the stools. Clonidine has been reported to lessen diabetic diarrhea; however, its usefulness is limited by its tendency to lower blood pressure in these patients who already have autonomic neuropathy, resulting in orthostatic hypotension. Constipation usually responds to stimulant laxatives such as senna. Bethanechol in doses of 10–50 mg three times a day has occasionally improved emptying of the atonic urinary bladder. Catheter decompression of the distended bladder has been reported to improve its function, and considerable benefit has been reported after surgical severing of the internal vesicle sphincter. Mineralocorticoid therapy with fludrocortisone, 0.2–0.3 mg/d, and elastic stockings or pressure suits have reportedly been of some help in patients with orthostatic hypotension occurring as a result of loss of postural reflexes.

Management of erectile dysfunction

There are medical, mechanical, and surgical treatments available for treatment of erectile dysfunction. Penile erection depends on relaxation of the smooth muscle in the arteries of the corpus cavernosum, and this is mediated by nitric oxide-induced cyclic 3',5'-guanosine monophosphate (cGMP) formation. cGMP-specific phosphodiesterase type 5 (PDE5) inhibitors impair the breakdown of cGMP and improve the ability to attain and maintain an erection. Sildenafil (Viagra), vardenafil (Levitra), and tadalafil (Cialis) have been shown in placebo-controlled clinical trials to improve erections in response to sexual stimulation. The recommended dose of sildenafil for most patients is one 50-mg tablet taken approximately 1 hour before sexual activity. The peak effect is at 1.5–2 hours, with some effect persisting for 4 hours. Patients with diabetes mellitus using sildenafil reported 50–60% improvement in erectile function. The maximum recommended dose is 100 mg. The recommended dose of both vardenafil and tadalafil is 10 mg. The doses may be increased to 20 mg or decreased to 5 mg based on efficacy and side effects. Tadalafil has been shown to improve erectile function for up to 36 hours after dosing. In clinical trials, only a few adverse effects have been reported—transient mild headache, flushing, dyspepsia, and some altered color vision. Priapism can occur with these drugs and patients should be advised to seek immediate medical attention if an erection persists for longer than 4 hours. The PDE5 inhibitors potentiate the hypotensive effects of nitrates and their use is contraindicated in patients who are concurrently using organic nitrates in any form. Caution is advised for men who have suffered a heart attack, stroke, or life-threatening arrhythmia within the previous 6 months; men who have resting hypotension or hypertension; and men who have a history of cardiac failure or have unstable angina. Rarely, a decrease in vision or permanent visual loss has been reported after PDE5 inhibitor use.

Intracorporeal injection of vasoactive drugs causes penile engorgement and erection. Drugs most commonly used include papaverine alone, papaverine with phentolamine, and alprostadil (prostaglandin E1). Alprostadil injections are relatively painless, but careful instruction is essential to prevent local trauma, priapism, and fibrosis.

Intraurethral pellets of alprostadil avoid the problem of injection of the drug.

External vacuum therapy (Erec-Aid System) is a nonsurgical treatment consisting of a suction chamber operated by a hand pump that creates a vacuum around the penis. This draws blood into the penis to produce an erection which is maintained by a specially designed tension ring inserted around the base of the penis and which can be kept in place for up to 20–30 minutes. While this method is generally effective, its cumbersome nature limits its appeal.

In view of the recent development of nonsurgical approaches to therapy of erectile dysfunction, resort to surgical implants of penile prostheses is becoming less common.

Cardiovascular Complications

Heart disease

Microangiopathy occurs in the heart and may explain the etiology of congestive cardiomyopathies in diabetic patients who do not have demonstrable coronary artery disease. More commonly, however, heart disease in patients with diabetes is due to coronary atherosclerosis. Myocardial infarction is three to five times more common in diabetic patients and is the leading cause of death in patients with type 2 diabetes. Cardiovascular disease risk is increased in patients with type 1 diabetes as well, although the absolute risk is lower than in patients with type 2 diabetes. Premenopausal women who normally have lower rates of coronary artery disease lose this protection once diabetes develops. The increased risk in patients with type 2 diabetes reflects the combination of hyperglycemia, hyperlipidemia, abnormalities of platelet adhesiveness, coagulation factors, hypertension, oxidative stress, and inflammation. Large intervention studies of risk factor reduction in diabetes are lacking, but it is reasonable to assume that reducing these risk factors would have a beneficial effect. Lowering LDL cholesterol reduces first events in patients without known coronary disease and secondary events in patients with known coronary disease. These intervention studies included some patients with diabetes, and the benefits of LDL cholesterol lowering was apparent in this group. The National Cholesterol Education Program clinical practice guidelines have designated diabetes as a coronary risk equivalent and have recommended that patients with diabetes should have an LDL cholesterol goal of < 100 mg/dL.

The ADA also recommends lowering blood pressure to 130/80 mm Hg or less. The Heart Outcomes Prevention Evaluation (HOPE) study randomized 9297 high-risk patients who had evidence of vascular disease or diabetes plus one other cardiovascular risk factor to receive ramipril or placebo for a mean of 5 years. Treatment with ramipril resulted in a 25% reduction of the risk of myocardial infarction, stroke, or death from cardiovascular disease. The mean difference between the placebo and ramipril group was 2.2 mm Hg systolic and 1.4 mm Hg diastolic blood pressure. The reduction in cardiovascular event rate remained significant after adjustment for this small difference in blood pressure. The mechanism underlying this protective effect of ramipril is unknown. Patients with type 2 diabetes who already have cardiovascular disease or microalbuminuria should therefore be considered for treatment with an ACE inhibitor. More clinical studies are needed to address the question of whether patients with type 2 diabetes who do not have cardiovascular disease or microalbuminuria would specifically benefit from ACE inhibitor treatment.

Aspirin at a dose of 81–325 mg daily has been shown to effectively inhibit thromboxane synthesis by platelets and reduce the risk of diabetic atherothrombosis without increasing risks of gastrointestinal hemorrhage. Use of low-dose enteric-coated aspirin is recommended in diabetic adults with evident macrovascular disease or in those with increased cardiovascular risk factors or those older than 30 years. Contraindications for aspirin therapy are patients with aspirin allergy, bleeding tendency, recent gastrointestinal bleeding, or active hepatic disease. The Early Treatment Diabetic Retinopathy Study (ETDRS) showed that aspirin does not influence the course of proliferative retinopathy. There was no statistically significant difference in the severity of vitreous/preretinal hemorrhages or their rate of resolution between the aspirin and placebo groups. Thus, it appears that there is no contraindication to aspirin use to achieve cardiovascular benefit in diabetic patients who have proliferative retinopathy.

Peripheral vascular disease

Atherosclerosis is markedly accelerated in the larger arteries. It is often diffuse, with localized enhancement in certain areas of turbulent blood flow, such as at the bifurcation of the aorta or other large vessels. Clinical manifestations of peripheral vascular disease include ischemia of the lower extremities, impotence, and intestinal angina.

The incidence of **gangrene of the feet** in diabetics is 30 times that in age-matched controls. The factors responsible for its development, in addition to peripheral vascular disease, are small vessel disease, peripheral neuropathy with loss of both pain sensation and neurogenic inflammatory responses, and secondary infection. In two-thirds of patients with ischemic gangrene, pedal pulses are not palpable. In the remaining one-third who have palpable pulses, reduced blood flow through these vessels can be demonstrated by plethysmographic or Doppler ultrasound examination. Prevention of foot injury is imperative. Agents that reduce peripheral blood flow such as tobacco and propranolol should be avoided. Control of other risk factors such as hypertension is essential. Cholesterol-lowering agents are useful as adjunctive therapy when early ischemic signs are detected and when dyslipidemia is present. Patients should be advised to seek immediate medical care if a diabetic foot ulcer develops. Improvement in peripheral blood flow with endarterectomy and bypass operations is possible in certain patients.

Skin and Mucous Membrane Complications

Chronic pyogenic infections of the skin may occur, especially in poorly controlled diabetic patients. Eruptive xanthomas can result from hypertriglyceridemia, associated with poor glycemic control. An unusual lesion termed **necrobiosis lipoidica diabeticorum** is usually located over the anterior surfaces of the legs or the dorsal surfaces of the ankles. They are oval or irregularly shaped plaques with demarcated borders and a glistening yellow surface and occur in women two to four times more frequently than in men.

"Shin spots" are not uncommon in adult diabetics. They are brownish, rounded, painless atrophic lesions of the skin in the pretibial area. Candidal infection can produce erythema and edema of intertriginous areas below the breasts, in the axillas, and between the fingers. It causes vulvovaginitis in most chronically uncontrolled diabetic women with persistent glucosuria and is a frequent cause of pruritus.

While antifungal creams containing miconazole or clotrimazole offer immediate relief of vulvovaginitis, recurrence is frequent unless glucosuria is reduced.

Special Situations

Insulin replacement during surgery

A number of studies have observed that hospitalized patients with diabetes and those with new-onset hyperglycemia (ie, those without a preadmission diagnosis of diabetes) have higher inpatient morbidity and mortality. These observations have led to the question of whether tight glycemic control in the hospital improves outcomes.

A prospective trial in surgical ICU patients (Leuven 1 study) reported that aggressive treatment of hyperglycemia (blood glucose > 110 mg/dL) reduced mortality and morbidity. Only a small number of persons in this study (204 of 1548) had a diagnosis of diabetes preoperatively, and so this study suggests that controlling hyperglycemia per se (independent of a diagnosis of diabetes) was beneficial. The benefits, however, were principally seen in patients who were in the ICU for longer than 5 days, and it is unclear whether the benefits also apply to most surgical patients who stay in the ICU for only 1 to 2 days.

The same investigators performed a similar prospective trial among 1200 medical ICU patients (Leuven 2 study) and reported that aggressive treatment of hyperglycemia reduced morbidity (decreased acquired kidney injury and increased early weaning from mechanical ventilation) but not mortality. Again, as in the surgical ICU study, only a small number of persons (16.9%) had a diagnosis of diabetes at admission. One of the inclusion criteria for the study was that patients would only be enrolled if they were likely to stay in the ICU for 3 days or longer. Some patients stayed in the ICU less than 3 days, and in that subgroup, intensive insulin therapy was associated with *increased* mortality. On the other hand, patients who stayed in the ICU for 3 days or longer had *reduced* mortality (and morbidity).

The findings of the Leuven studies have not been independently confirmed. Two other ICU-based studies (Glucontrol and VISEP) that attempted to confirm the findings were unable to do so. These two studies, however, were stopped prematurely for the following reasons: an interim analysis (falsely) suggested increased mortality in the test group in the Glucontrol study and hypoglycemic events increased sevenfold in the intensive treatment group in the VISEP study.

A study on tight intraoperative glycemic control during cardiac surgery also failed to show any benefit; if anything, the intensively treated group had more events. The United Kingdom Glucose Insulin in Stroke Trial (GIST-UK) failed to show beneficial effect of tight glycemic control in stroke patients; however, the investigators acknowledged that, because of slow recruitment, the study was underpowered. A large multicenter, multinational study (NICE-SUGAR) is currently reenrolling patients and the results of this study will hopefully resolve the question of how tightly to control glucose levels in the ICU.

Thus, based on the evidence available so far, keeping blood glucose values close to 100 mg/dL should be considered in the surgical and medical ICUs. When patients leave the ICU, target glucose values between 100 mg/dL and 180 mg/dL may be appropriate, although this view is based on clinical observations rather than conclusive evidence.

During major surgery and in the immediate recovery period in patients with type 1 diabetes—and in most patients with type 2 diabetes—regular insulin (25 units insulin in 250 mL 0.9% saline) is infused at a rate of 1–3 units/h. The insulin infusion is "piggy backed" onto a 5% dextrose in physiologic saline containing 20 mEq of potassium chloride, which is infused intravenously at a rate of ~100 mL/h. The patient's blood glucose should be monitored every 30 minutes to 2 hours and the insulin dose adjusted to maintain target blood glucose levels. Type 2 patients facing minor surgical procedures not requiring general anesthesia who have previously been controlled on oral agents or diet alone do not generally require insulin infusions. Glucose-containing solutions should be avoided during surgery in these patients, and blood glucose levels should be monitored every 4 hours. Regular human insulin or one of the rapidly acting insulin analogs should be administered subcutaneously if needed to maintain blood glucose below 200 mg/dL (see Chapter 3: Preoperative Evaluation & Perioperative Management).

Pregnancy and the diabetic patient

Tight glycemic control with normal HbA_{1c} levels is very important during pregnancy. Early in pregnancy, poor control increases the risk of spontaneous abortion and congenital malformations. Late in pregnancy, poor control can result in polyhydramnios, preterm labor, stillbirth, and fetal macrosomia with its associated problems. Diabetes complications can impact both maternal and fetal health. Diabetic retinopathy can first develop during pregnancy or retinopathy that is already present can worsen. Diabetic women with microalbuminuria can have worsening albuminuria during pregnancy and are at higher risk for preeclampsia. Patients who have preexisting kidney failure (prepregnancy creatinine clearance less than 80 mL/min) are at high risk for further decline in kidney function during the pregnancy, and this may not reverse after delivery. Diabetic gastroparesis can severely exacerbate the nausea and vomiting of pregnancy and some patients may require fluid and nutritional support.

Although there is evidence that glyburide is safe during pregnancy, the current practice is to control diabetes with insulin therapy. Every effort should be made, utilizing multiple injections of insulin or a continuous infusion of insulin by pump, to maintain near-normalization of fasting and preprandial blood glucose values while avoiding hypoglycemia. The fast-acting insulin analogs insulin aspart and insulin lispro can be used, but data on using the long-acting insulin analogs are limited. A small study using insulin glargine in 32 pregnancies did not reveal any problems. There are no data on insulin detemir use in pregnancy. NPH is currently the preferred intermediate insulin for basal coverage during pregnancy.

Unless there are fetal or maternal complications, diabetic women should be able to carry the pregnancy to full-term, delivering at 38 to 41 weeks. Induction of labor before 39 weeks may be considered if there is concern about increasing fetal weight. See Chapter 19: Obstetrics & Obstetric Disorders for further details.

Prognosis

The DCCT showed that the previously poor prognosis for as many as 40% of patients with type 1 diabetes is markedly improved by optimal care. DCCT participants were generally young and highly motivated and were cared for in academic centers by skilled diabetes educators and endocrinologists who were able to provide more attention and services than are usually available. Improved training of primary care providers may be beneficial.

For type 2 diabetes, the UKPDS documented a reduction in microvascular disease with glycemic control, although this was not apparent in the obese subgroup. Cardiovascular outcomes were not improved by glycemic control, although antihypertensive therapy showed benefit in reducing the number of adverse cardiovascular complications as well as in reducing the occurrence of microvascular disease among hypertensive patients. In patients with visceral obesity, successful management of type 2 diabetes remains a major challenge in the attempt to achieve appropriate control of hyperglycemia, hypertension, and dyslipidemia. Once safe and effective methods are devised to prevent or manage obesity, the prognosis of type 2 diabetes with its high cardiovascular risks should improve considerably.

In addition to poorly understood genetic factors relating to differences in individual susceptibility to development of long-term complications of hyperglycemia, it is clear that in both types of diabetes, the diabetic patient's intelligence, motivation, and awareness of the potential complications of the disease contribute significantly to the ultimate outcome.

Diabetic Coma: Introduction

Coma may be due to a variety of causes not directly related to diabetes. Certain causes directly related to diabetes require differentiation: (1) Hypoglycemic coma resulting from excessive doses of insulin or oral hypoglycemic agents. (2) Hyperglycemic coma associated with either severe insulin deficiency (diabetic ketoacidosis) or mild to moderate insulin deficiency (hyperglycemic hyperosmolar state). (3) Lactic acidosis associated with diabetes, particularly in diabetics stricken with severe infections or with cardiovascular collapse.

Diabetic Ketoacidosis

Essentials of Diagnosis

- Hyperglycemia > 250 mg/dL.
- Acidosis with blood pH < 7.3.
- Serum bicarbonate < 15 mEq/L.
- Serum positive for ketones.

General Considerations

Diabetic ketoacidosis may be the initial manifestation of type 1 diabetes or may result from increased insulin requirements in type 1 diabetes patients during the course of infection, trauma, myocardial infarction, or surgery. It is a life-threatening medical emergency with a mortality rate just under 5% in individuals under 40 years of age, but with a more serious prognosis in the elderly, who have mortality rates over 20%. The National Data Group report an annual incidence of five to eight episodes of diabetic ketoacidosis per 1000 diabetic persons. Ketoacidosis may develop in patients with type 2 diabetes when severe stress such as sepsis or trauma is present. Diabetic ketoacidosis has been found to be one of the more common serious complications of insulin pump therapy, occurring in approximately 1 per 80 patient-months of treatment. Many patients who monitor capillary blood glucose regularly ignore urine ketone measurements, which would signal the possibility of insulin leakage or pump failure before serious illness develops. Poor compliance is one of the most common causes of diabetic ketoacidosis, particularly when episodes are recurrent.

Clinical Findings

Symptoms and Signs

The appearance of diabetic ketoacidotic coma is usually preceded by a day or more of polyuria and polydipsia associated with marked fatigue, nausea and vomiting, and, finally, mental stupor that can progress to coma. On physical examination, evidence of dehydration in a stuporous patient with rapid deep breathing and a "fruity" breath odor of acetone would strongly suggest the diagnosis. Hypotension with tachycardia indicates profound fluid and electrolyte depletion, and mild hypothermia is usually present. Abdominal pain and even tenderness may be present in the absence of abdominal disease. Conversely, cholecystitis or pancreatitis may occur with minimal symptoms and signs.

Laboratory Findings

(Table 27–13.) Glycosuria of 4+ and strong ketonuria with hyperglycemia, ketonemia, low arterial blood pH, and low plasma bicarbonate are typical of diabetic ketoacidosis. Serum potassium is often elevated despite total body potassium depletion resulting from protracted polyuria or vomiting. Elevation of serum amylase is common but often represents salivary as well as pancreatic amylase. Thus, in this setting, an elevated serum amylase is not specific for acute pancreatitis. Serum lipase may be useful if the diagnosis of acute pancreatitis is being seriously considered. Azotemia may be a better indicator of renal status than serum creatinine, since multichannel chemical analysis of serum creatinine (SMA-6) is falsely elevated by nonspecific chromogenicity of keto acids and glucose. Most laboratories, however, now routinely eliminate this interference. Leukocytosis as high as 25,000/mcL with a left shift may occur with or without associated infection. The presence of an elevated or even a normal temperature would suggest the presence of an infection, since patients with diabetic ketoacidosis are generally hypothermic if uninfected.

Table 27–13. Laboratory diagnosis of coma in diabetic patients.

	Urine		**Plasma**		
	Glucose	**Acetone**	**Glucose**	**Bicarbonate**	**Acetone**
Related to diabetes					

Hypoglycemia	0[1]	0 or +	Low	Normal	0
Diabetic ketoacidosis	++++	++++	High	Low	++++
Hyperglycemic hyperosmolar state coma	++++	0	High	Normal or slightly low	0
Lactic acidosis	0 or +	0 or +	Normal or low or high	Low	0 or +
Unrelated to diabetes					
Alcohol or other toxic drugs	0 or +	0 or +	May be low	Normal or low[2]	0 or +
Cerebrovascular accident or head trauma	+ or 0	0	Often high	Normal	0
Uremia	0 or +	0	High or normal	Low	0 or +

[1] Leftover urine in bladder might still contain glucose from earlier hyperglycemia.

[2] Alcohol can elevate plasma lactate as well as keto acids to reduce pH.

Complications

Hyperglycemia and ketoacidemia are due to insulin lack, hyperglucagonemia, and elevated levels of the stress hormones catecholamines, cortisol, and growth hormone.

Hyperglycemia

Hyperglycemia results from increased hepatic production of glucose as well as diminished glucose uptake by peripheral tissues. Hepatic glucose output is a consequence of increased gluconeogenesis resulting from insulinopenia as well as from an associated hyperglucagonemia.

Ketoacidemia

Ketoacidemia represents the effect of insulin lack at multiple enzyme loci. Insulin lack associated with elevated levels of growth hormone, catecholamines, and glucagon contributes to an increase in lipolysis from adipose tissue and in hepatic ketogenesis. In addition, there is evidence that reduced ketolysis by insulin-deficient peripheral tissues contributes to the ketoacidemia. The only true "keto" acid present is acetoacetic acid, which, along with its by-product acetone, is measured by nitroprusside reagents (Acetest and Ketostix). The sensitivity for acetone, however, is poor, requiring over 10 mmol, which is seldom reached in the plasma of ketoacidotic subjects—although this detectable concentration is readily achieved in urine. Thus, in the plasma of ketotic patients, only acetoacetate is measured by these reagents. The more prevalent -hydroxybutyric acid has no ketone group and is therefore not detected by conventional nitroprusside tests. This takes on special importance in the presence of circulatory collapse during diabetic ketoacidosis, wherein an increase in lactic acid can shift the redox state to increase -hydroxybutyric acid at the expense of the readily detectable acetoacetic acid. Bedside diagnostic reagents would then be unreliable, suggesting no ketonemia in cases where -hydroxybutyric acid is a major factor in producing the acidosis. A combined glucose and ketone meter (Precision Xtra, Abbott Diabetes Care) that is able to measure blood -hydroxybutyrate concentration on capillary blood is available. Many clinical laboratories now offer -hydroxybutyrate measurement.

Fluid and Electrolyte Depletion

Hyperglycemia results in an osmotic diuresis and dehydration and secondary loss of electrolytes. Ketonuria similarly causes loss of water and electrolytes. Balance studies during withdrawal of insulin and treatment in patients with type 1 diabetes show that on average the water depletion is about 5 L; sodium, 300–500 mmol; potassium, 270–400 mmol; chloride, 100–400 mmol.

Drowsiness is fairly common but frank coma only occurs in about 10% of patients. There is a correlation between the degree of depression of the sensorium and extracellular osmolarity. When serum hyperosmolality exceeds 320–330 mosm/L, central nervous system depression or coma may ensue. Coma in a diabetic patient with a lower osmolality should prompt a search for cause of coma other than hyperosmolality.

Treatment

Prevention

Education of diabetic patients to recognize the early symptoms and signs of ketoacidosis has done a great deal to prevent severe acidosis. Urine ketones or capillary blood -hydroxybutyrate should be measured in patients with signs of infection or in insulin pump-treated patients when capillary blood glucose is unexpectedly and persistently high. When heavy ketonuria and glycosuria persist on several successive examinations, supplemental regular insulin should be administered and liquid foods such as lightly salted tomato juice and broth should be ingested to replenish fluids and electrolytes. The patient should be instructed to contact the physician if ketonuria persists, and especially if vomiting develops or if appropriate adjustment of the infusion rate on an insulin pump does not correct the hyperglycemia and ketonuria. In juvenile-onset diabetics, particularly in the teen years, recurrent episodes of severe ketoacidosis often indicate poor compliance with the insulin regimen, and these patients will require intensive family counseling.

Emergency Measures

If ketosis is severe, the patient should be placed in the hospital for correction of the hyperosmolality as well as the ketoacidemia. An ICU or, at the least, a step-down unit is preferable for more severe cases.

Therapeutic flow sheet

One of the most important steps in initiating therapy is to start a flow sheet listing vital signs and the time sequence of diagnostic laboratory values in relation to therapeutic maneuvers. Indices of the metabolic defects include urine glucose and ketones as well as arterial pH, plasma glucose, acetone, bicarbonate, serum urea nitrogen, and electrolytes. Serum osmolality should be measured or estimated and tabulated during the course of therapy.

A convenient method of estimating effective serum osmolality is as follows (normal values in humans are 280–300 mosm/kg):

These calculated estimates are usually 10–20 mosm/kg lower than values measured by standard cryoscopic techniques in patients with diabetic coma. Urea is freely permeable across cell membranes and therefore not included in calculations of effective serum osmolality. One physician should be responsible for maintaining this therapeutic flow sheet and prescribing therapy. An indwelling urinary catheter is required in all comatose patients but should be avoided if possible in a fully cooperative diabetic because of the risk of introducing bladder infection. Fluid intake and output should be recorded. Gastric intubation is recommended in the comatose patient to correct the commonly associated gastric dilatation that may lead to vomiting and aspiration. The patient should not receive sedatives or opioids.

Insulin replacement

Only regular insulin should be used initially in all cases of severe ketoacidosis, and it should be given immediately after the diagnosis is established. Regular insulin can be given in a loading dose of 0.15 unit/kg as an intravenous bolus to prime the tissue insulin receptors. Following the initial bolus, doses of insulin as low as 0.1 unit/kg/h are continuously infused or given hourly as an intramuscular injection; this is sufficient to replace the insulin deficit in most patients. Replacement of insulin deficiency helps correct the acidosis by reducing the flux of fatty acids to the liver, reducing ketone production by the liver, and also improving removal of ketones from the blood. Insulin treatment reduces the hyperosmolality by reducing the hyperglycemia. It accomplishes this by increasing removal of glucose through peripheral utilization as well as by decreasing production of glucose by the liver. This latter effect is accomplished by direct inhibition of gluconeogenesis and glycogenolysis, as well as by lowered amino acid flux from muscle to liver and reduced hyperglucagonemia.

The insulin dose should be "piggy-backed" into the fluid line so the rate of fluid replacement can be changed without altering the insulin delivery rate. If the plasma glucose level fails to fall at least 10% in the first hour, a repeat loading dose is recommended. The availability of bedside glucometers and of laboratory instruments for rapid and accurate glucose analysis (Beckman or Yellow Springs glucose analyzer) has contributed much to achieving optimal insulin replacement. Rarely, a patient with immune insulin resistance is encountered, and this requires doubling the insulin dose every 2–4 hours if hyperglycemia does not improve after the first two doses of insulin.

Fluid replacement

In most patients, the fluid deficit is 4–5 L. Initially, 0.9% saline solution is the solution of choice to help reexpand the contracted vascular volume and should be started in the emergency department as soon as the diagnosis is established. The saline should be infused rapidly to provide 1 L/h over the first 1–2 hours. After the first 2 L of fluid have been given, the intravenous infusion should be at the rate of 300–400 mL/h. Use 0.9 % ("normal") saline unless the serum sodium is greater than 150 mEq/L, when 0.45% ("half normal") saline solution should be used. The volume status should be very carefully monitored. Failure to give enough volume replacement (at least 3–4 L in 8 hours) to restore normal perfusion is one of the most serious therapeutic shortcomings adversely influencing satisfactory recovery. Excessive fluid replacement (more than 5 L in 8 hours) may contribute to acute respiratory distress syndrome or cerebral edema. When blood glucose falls to approximately 250 mg/dL, the fluids should be changed to a 5% glucose-containing solution to maintain serum glucose in the range of 250–300 mg/dL. This will prevent the development of hypoglycemia and will also reduce the likelihood of cerebral edema, which could result from too rapid decline of blood glucose. Intensive insulin therapy should be continued until the ketoacidosis is corrected.

Sodium bicarbonate

The use of sodium bicarbonate in management of diabetic ketoacidosis has been questioned since clinical benefit was not demonstrated in one prospective randomized trial and because of the following potentially harmful consequences: (1) development of hypokalemia from rapid shift of potassium into cells if the acidosis is overcorrected, (2) tissue anoxia from reduced dissociation of oxygen from hemoglobin when acidosis is rapidly reversed (leftward shift of the oxygen dissociation curve), and (3) cerebral acidosis resulting from lowering of cerebrospinal fluid pH. It must be emphasized, however, that these considerations are less important when severe acidosis exists. It is therefore recommended that bicarbonate be administered to diabetic patients in ketoacidosis if the arterial blood pH is 7.0 or less, with careful monitoring to prevent overcorrection. One or two ampules of sodium bicarbonate (one ampule contains 44 mEq/50 mL) should be added to 1 L of 0.45% saline. (**Note:** Addition of sodium bicarbonate to 0.9% saline would produce a markedly hypertonic solution that could aggravate the hyperosmolar state already present.) This should be administered rapidly (over the first hour). It can be repeated until the arterial pH reaches 7.1, but *it should not be given if the pH is 7.1 or greater* since additional bicarbonate would increase the risk of rebound metabolic alkalosis as ketones are metabolized. Alkalosis shifts potassium from serum into cells, which could precipitate a fatal cardiac arrhythmia.

Potassium

Total body potassium loss from polyuria and vomiting may be as high as 200 mEq. However, because of shifts of potassium from cells into the extracellular space as a consequence of acidosis, serum potassium is usually normal to slightly elevated prior to institution of treatment. As the acidosis is corrected, potassium flows back into the cells, and hypokalemia can develop if potassium replacement is not instituted. If the patient is not uremic and has an adequate urinary output, potassium chloride in doses of 10–30 mEq/h should be infused during the second and third hours after beginning therapy as soon as the acidosis starts to resolve. Replacement should be started sooner if the initial serum potassium is inappropriately normal or low and should be delayed if serum potassium fails to respond to initial therapy and remains above 5 mEq/L, as in cases of chronic kidney disease. An ECG can be of help in monitoring the patient's potassium status: High peaked T waves are a sign of hyperkalemia, and flattened T waves with U waves are a sign of hypokalemia. Foods high in potassium content should be prescribed when the patient has recovered sufficiently to take food orally. Tomato juice has 14 mEq of potassium per 240 mL, and a medium-sized banana provides about 10 mEq.

Phosphate

Phosphate replacement is seldom required in treating diabetic ketoacidosis. However, if severe hypophosphatemia of less than 1 mg/dL (< 0.32 mmol/L) develops during insulin therapy, a small amount of phosphate can be replaced per hour as the potassium salt. Correction of hypophosphatemia helps restore the buffering capacity of the plasma, thereby facilitating renal excretion of hydrogen. It also corrects the impaired oxygen dissociation from hemoglobin by regenerating 2,3-diphosphoglycerate. However, three randomized studies in which phosphate was replaced in only half of a group of patients with diabetic ketoacidosis did not show any apparent clinical benefit from phosphate administration. Moreover, attempts to use the phosphate salt of potassium as the sole means of replacing potassium have led to a number of reported cases of severe hypocalcemia with tetany. To minimize the risk of inducing tetany from too-rapid replacement of phosphate, the average deficit of 40–50 mmol of phosphate should be replaced intravenously at a rate *no greater than 3–4 mmol/h* in a 60–70-kg person. A stock solution (Abbott) provides a mixture of 1.12 g KH_2PO_4 and 1.18 g K_2HPO_4 in a 5-mL single-dose vial (this equals 22 mmol of potassium and 15 mmol of phosphate). One-half of this vial (2.5 mL) should be added to 1 L of either 0.45% saline or 5% dextrose in water. Two liters of this solution, infused at a rate of 400 mL/h, will correct the phosphate deficit at the optimal rate of 3 mmol/h while providing 4.4 mEq of potassium per hour. (Additional potassium should be administered as potassium chloride to provide a total of 10–30 mEq of potassium per hour, as noted above.) If the serum phosphate remains below 2.5 mg/dL after this infusion, a repeat 5-hour infusion can be given.

Hyperchloremic acidosis during therapy

Because of the considerable loss of keto acids in the urine during the initial phase of therapy, substrate for subsequent regeneration of bicarbonate is lost and correction of the total bicarbonate deficit is hampered. A portion of the bicarbonate deficit is replaced with chloride ions infused in large amounts as saline to correct the dehydration. In most patients, as the ketoacidosis clears during insulin replacement, a hyperchloremic, low-bicarbonate pattern emerges with a normal anion gap. This is a relatively benign condition that reverses itself over the subsequent 12–24 hours once intravenous saline is no longer being administered.

Treatment of associated infection

Antibiotics are prescribed as indicated. Cholecystitis and pyelonephritis may be particularly severe in these

patients.

Prognosis

The frequency of deaths due to diabetic ketoacidosis has been dramatically reduced by improved therapy of young diabetics, but this complication remains a significant risk in the aged and in patients in profound coma in whom treatment has been delayed. Acute myocardial infarction and infarction of the bowel following prolonged hypotension worsen the outlook. A serious prognostic sign is end-stage chronic kidney disease, and prior kidney dysfunction worsens the prognosis considerably because the kidney plays a key role in compensating for massive pH and electrolyte abnormalities. Cerebral edema has been reported to occur rarely as metabolic deficits return to normal. This is best prevented by avoiding sudden reversal of marked hyperglycemia. Maintaining glycemic levels of 200–300 mg/dL for the initial 24 hours after correction of severe hyperglycemia reduces this risk.

Kitabchi AE et al: Management of hyperglycemic crises in patients with diabetes. Diabetes Care 2001;24:131. [PMID: 11194218]

Hyperglycemic Hyperosmolar State

Essentials of Diagnosis

- Hyperglycemia > 600 mg/dL.

- Serum osmolality > 310 mosm/kg.
- No acidosis; blood pH above 7.3.
- Serum bicarbonate > 15 mEq/L.
- Normal anion gap (< 14 mEq/L).

General Considerations

This second most common form of hyperglycemic coma is characterized by severe hyperglycemia in the absence of significant ketosis, with hyperosmolality and dehydration. It occurs in patients with mild or occult diabetes, and most patients are at least middle-aged to elderly. Accurate figures are not available as to its true incidence, but from data on hospital discharges it is rarer than diabetic ketoacidosis even in older age groups. Lethargy and confusion develop as serum osmolality exceeds 310 mosm/kg, and coma can occur if osmolality exceeds 320–330 mosm/kg. A committee of the ADA has recommended replacing the previous name of this disorder (hyperglycemic, hyperosmolar, nonketotic coma) with the consensus term "hyperglycemic hyperosmolar state." Underlying chronic kidney disease or congestive heart failure is common, and the presence of either worsens the prognosis. A precipitating event such as infection, myocardial infarction, stroke, or recent operation is often present. Certain drugs such as phenytoin, diazoxide, corticosteroids, and diuretics have been implicated in its pathogenesis, as have procedures associated with glucose loading such as peritoneal dialysis.

Pathogenesis

A partial or relative insulin deficiency may initiate the syndrome by reducing glucose utilization of muscle, fat, and liver while inducing hyperglucagonemia and increasing hepatic glucose output. With massive glycosuria, obligatory water loss ensues. If a patient is unable to maintain adequate fluid intake because of an associated acute or chronic illness or has suffered excessive fluid loss, marked dehydration results. As plasma volume contracts, chronic kidney disease develops, and the resultant limitation of renal glucose loss leads to increasingly higher blood glucose concentrations. Severe hyperosmolality develops that causes mental confusion and finally coma. It is not clear why ketosis is virtually absent under these conditions of insulin insufficiency, although reduced levels of growth hormone may be a factor, along with portal vein insulin concentrations sufficient to restrain ketogenesis.

Clinical Findings

Symptoms and Signs

Onset may be insidious over a period of days or weeks, with weakness, polyuria, and polydipsia. The lack of features of ketoacidosis may retard recognition of the syndrome and delay therapy until dehydration becomes more profound than in ketoacidosis. Reduced intake of fluid is not an uncommon historical feature, due to either inappropriate lack of thirst, nausea, or inaccessibility of fluids to elderly, bedridden patients. Lethargy and confusion develop, progressing to convulsions and deep coma. Physical examination confirms the presence of profound dehydration in a lethargic or comatose patient without Kussmaul respirations.

Laboratory Findings

(Table 27–13.) Severe hyperglycemia is present, with blood glucose values ranging from 600 to 2400 mg/dL. In mild cases, where dehydration is less severe, dilutional hyponatremia as well as urinary sodium losses may reduce serum sodium to 120–125 mEq/L, which protects to some extent against extreme hyperosmolality. However, as dehydration progresses, serum sodium can exceed 140 mEq/L, producing serum osmolality readings of 330–440 mosm/kg. Ketosis and acidosis are usually absent or mild. Prerenal azotemia is the rule, with serum urea nitrogen elevations over 100 mg/dL being typical.

Treatment

Saline

Fluid replacement is of paramount importance in treating nonketotic hyperglycemic coma. The onset of hyperosmolarity is more insidious in elderly people without ketosis than in younger individuals with high serum ketone levels, which provide earlier indicators of severe illness (vomiting, rapid deep breathing, acetone odor, etc). Consequently, diagnosis and treatment are often delayed until fluid deficit has reached levels of 6–10 L.

If hypovolemia is present as evidenced by hypotension and oliguria, fluid therapy should be initiated with 0.9% saline. In all other cases, 0.45% saline appears to be preferable as the initial replacement solution because the body fluids of these patients are markedly hyperosmolar. As much as 4–6 L of fluid may be required in the first 8–10 hours. Careful monitoring of the patient is required for proper sodium and water replacement. Once blood glucose reaches 250 mg/dL, fluid replacement should include 5% dextrose in either water, 0.45% saline solution, or 0.9% saline solution. The rate of dextrose infusion should be adjusted to maintain glycemic levels of 250–300 mg/dL in order to reduce the risk of cerebral edema. An important end point of fluid therapy is to restore urinary output to 50 mL/h or more.

Insulin

Less insulin may be required to reduce the hyperglycemia in nonketotic patients as compared to those with diabetic ketoacidotic coma. In fact, fluid replacement alone can reduce hyperglycemia considerably by correcting the hypovolemia, which then increases both glomerular filtration and renal excretion of glucose. An initial dose of 0.15 unit/kg is followed by an insulin infusion of 1–2 units/h, which is titrated to lower blood glucose levels by 50–70 mg/dL per hour.

Potassium

With the absence of acidosis, there may be no initial hyperkalemia unless associated end-stage chronic kidney disease is present. This results in less severe total potassium depletion than in diabetic ketoacidosis, and less potassium replacement is therefore needed. However, because initial serum potassium is usually not elevated and because it declines rapidly as a result of insulin's effect on driving potassium intracellularly, it has been recommended that potassium replacement be initiated earlier than in ketotic patients, assuming that no chronic kidney disease or oliguria is present. Potassium chloride (10 mEq/L) can be added to the initial bottle of fluids administered if the patient's serum potassium is not elevated.

Phosphate

If severe hypophosphatemia (serum phosphate < 1 mg/dL [< 0.32 mmol/L]) develops during insulin therapy, phosphate replacement can be given as described for ketoacidotic patients (at 3 mmol/h).

Prognosis

The overall mortality rate of hyperglycemic hyperosmolar, state coma is more than ten times that of diabetic ketoacidosis, chiefly because of its higher incidence in older patients, who may have compromised cardiovascular systems or associated major illnesses and whose dehydration is often excessive because of delays in recognition and treatment. (When patients are matched for age, the prognoses of these two hyperglycemic emergencies are reasonably comparable.) When prompt therapy is instituted, the mortality rate can be reduced from nearly 50% to that related to the severity of coexistent disorders.

American Diabetes Association. Hyperglycemic crises in patients with diabetes mellitus. Diabetes Care. 2001 Jan;24(1):154–61. [PMID: 11221603]

Lactic Acidosis

Essentials of Diagnosis

- Severe acidosis with hyperventilation.
- Blood pH below 7.30.
- Serum bicarbonate < 15 mEq/L.
- Anion gap > 15 mEq/L.
- Absent serum ketones.

- Serum lactate > 5 mmol/L.

General Considerations

Lactic acidosis is characterized by accumulation of excess lactic acid in the blood. Normally, the principal sources of this acid are the erythrocytes (which lack enzymes for aerobic oxidation), skeletal muscle, skin, and brain. Conversion of lactic acid to glucose and its oxidation principally by the liver but also by the kidneys represent the chief pathways for its removal. Overproduction of lactic acid (tissue hypoxia), deficient removal (hepatic failure), or both (circulatory collapse) can cause accumulation. Lactic acidosis is not uncommon in any severely ill patient suffering from cardiac decompensation, respiratory or hepatic failure, septicemia, or infarction of bowel or extremities. With the discontinuance of phenformin therapy in the United States, lactic acidosis in patients with diabetes mellitus has become uncommon but occasionally occurs in metformin-treated patients (see above) and it still must be considered in the acidotic diabetic, especially if the patient is seriously ill.

Clinical Findings

Symptoms and Signs

The main clinical feature of lactic acidosis is marked hyperventilation. When lactic acidosis is secondary to tissue hypoxia or vascular collapse, the clinical presentation is variable, being that of the prevailing catastrophic illness. However, in the idiopathic, or spontaneous, variety, the onset is rapid (usually over a few hours), blood pressure is normal, peripheral circulation is good, and there is no cyanosis.

Laboratory Findings

Plasma bicarbonate and blood pH are quite low, indicating the presence of severe metabolic acidosis. Ketones are usually absent from plasma and urine or at least not prominent. The first clue may be a high anion gap (serum sodium minus the sum of chloride and bicarbonate anions [in mEq/L] should be no greater than 15). A higher value indicates the existence of an abnormal compartment of anions. If this cannot be clinically explained by an excess of keto acids (diabetes), inorganic acids (uremia), or anions from drug overdosage (salicylates, methyl alcohol, ethylene glycol), then lactic acidosis is probably the correct diagnosis. (See Chapter 21: Fluid & Electrolyte Disorders also.) In the absence of azotemia, hyperphosphatemia may be a clue to the presence of lactic acidosis for reasons that are not clear. The diagnosis is confirmed by demonstrating, in a sample of blood that is promptly chilled and separated, a plasma lactic acid concentration of 5 mmol/L or higher (values as high as 30 mmol/L have been reported). Normal plasma values average 1 mmol/L, with a normal lactate/pyruvate ratio of 10:1. This ratio is greatly exceeded in lactic acidosis.*

*In collecting samples, it is essential to rapidly chill and separate the blood in order to remove red cells, whose continued glycolysis at room temperature is a common source of error in reports of high plasma lactate. Frozen plasma remains stable for subsequent assay.

Treatment

Aggressive treatment of the precipitating cause of lactic acidosis is the main component of therapy, such as ensuring adequate oxygenation and vascular perfusion of tissues. Empirical antibiotic coverage for sepsis should be given after culture samples are obtained in any patient in whom the cause of the lactic acidosis is not apparent.

Alkalinization with intravenous sodium bicarbonate to keep the pH above 7.2 has been recommended by some in the emergency treatment of lactic acidosis; as much as 2000 mEq in 24 hours has been used. However, there is no evidence that the mortality rate is favorably affected by administering bicarbonate, and its use remains controversial. Hemodialysis may be useful in cases where large sodium loads are poorly tolerated.

Prognosis

The mortality rate of spontaneous lactic acidosis is high. The prognosis in most cases is that of the primary disorder that produced the lactic acidosis.

Forsythe SM et al. Sodium bicarbonate for the treatment of lactic acidosis. Chest. 2000 Jan;117(1):260–7. [PMID: 10631227]

Salpeter S et al. Risk of fatal and nonfatal lactic acidosis with metformin use in type 2 diabetes mellitus. Cochrane Database Syst Rev. 2006 Jan 25;(1):CD002967. [PMID: 16437448]

The Hypoglycemic States: Introduction

Spontaneous hypoglycemia in adults is of two principal types: fasting and postprandial. Symptoms begin at plasma glucose levels in the range of 60 mg/dL and impairment of brain function at approximately 50 mg/dL. Fasting hypoglycemia is often subacute or chronic and usually presents with neuroglycopenia as its principal manifestation; postprandial hypoglycemia is relatively acute and is often heralded by symptoms of neurogenic autonomic discharge (sweating, palpitations, anxiety, tremulousness).

Differential Diagnosis

(Table 27–14) **Fasting hypoglycemia** may occur in certain endocrine disorders, such as hypopituitarism, Addison disease, or myxedema; in disorders related to liver malfunction, such as acute alcoholism or liver failure; and in instances of end-stage chronic kidney disease, particularly in patients requiring dialysis. These conditions are usually obvious, with hypoglycemia being only a secondary feature. When fasting hypoglycemia is a primary manifestation developing in adults without apparent endocrine disorders or inborn metabolic diseases from childhood, the principal diagnostic possibilities include: (1) hyperinsulinism, due to either pancreatic B cell tumors or islet hyperplasia or surreptitious administration of insulin (or sulfonylureas), and (2) hypoglycemia due to non–insulin-producing extrapancreatic tumors.

Table 27–14. Common causes of hypoglycemia in adults.[1]
Fasting hypoglycemia
Hyperinsulinism
Pancreatic B cell tumor
Surreptitious administration of insulin or sulfonylureas
Extrapancreatic tumors
Postprandial (reactive) hypoglycemia
Early hypoglycemia (alimentary)

Postgastrectomy
Functional (increased vagal tone)
Late hypoglycemia (occult diabetes mellitus)
Delayed insulin release due to B cell dysfunction
Counterregulatory hormone and neurogenic autonomic response deficiency
Idiopathic
Alcohol-related hypoglycemia
Immunopathologic hypoglycemia
Idiopathic anti-insulin antibodies (which release their bound insulin)
Antibodies to insulin receptors (which act as agonists)
Drug-induced hypoglycemia

[1] In the absence of clinically obvious endocrine, renal, or hepatic disorders and exclusive of diabetes mellitus treated with hypoglycemic agents.

Postprandial (reactive) hypoglycemia may be classified as early (within 2–3 hours after a meal) or late (3–5 hours after eating). Early, or alimentary, hypoglycemia occurs when there is a rapid discharge of ingested carbohydrate into the small bowel followed by rapid glucose absorption and hyperinsulinism. It may be seen after gastrointestinal surgery and is particularly associated with the dumping syndrome after gastrectomy and Roux-en-Y gastric bypass surgery. In some cases, it is functional and may represent overactivity of the parasympathetic nervous system mediated via the vagus nerve. Rarely, it results from defective counterregulatory responses such as deficiencies of growth hormone, glucagon, cortisol, or autonomic responses.

Alcohol-related hypoglycemia is due to hepatic glycogen depletion combined with alcohol-mediated inhibition of gluconeogenesis. It is most common in malnourished alcohol abusers but can occur in anyone who is unable to ingest food after an acute alcoholic episode followed by gastritis and vomiting.

Immunopathologic hypoglycemia is an extremely rare condition in which anti-insulin antibodies or antibodies to insulin receptors develop spontaneously. In the former case, the mechanism appears to relate to increasing dissociation of insulin from circulating pools of bound insulin. When antibodies to insulin receptors are found, most patients do not have hypoglycemia but rather severe insulin-resistant diabetes and acanthosis nigricans. However, during the course of the disease in these patients, certain anti-insulin receptor antibodies with agonist activity mimicking insulin action may develop, producing severe hypoglycemia.

Factitious hypoglycemia is self-induced hypoglycemia due to surreptitious administration of insulin or sulfonylureas.

Hypoglycemia Due to Pancreatic B Cell Tumors

Essentials of Diagnosis

- Hypoglycemic symptoms—frequently neuroglycopenic (confusion, blurred vision, diplopia, anxiety, convulsions).
- Immediate recovery upon administration of glucose.
- Blood glucose < 40 mg/dL with a serum insulin level of 6 microunit/mL or more.

General Considerations

Fasting hypoglycemia in an otherwise healthy, well-nourished adult is rare, and is most commonly due to an adenoma of the islets of Langerhans. Ninety percent of such tumors are single and benign, but multiple adenomas can occur as well as malignant tumors with functional metastases. Adenomas may be familial, and multiple adenomas have been found in conjunction with tumors of the parathyroids and pituitary (multiple endocrine neoplasia type 1 [MEN 1]).

Clinical Findings

Symptoms and Signs

The most important prerequisite to diagnosing an insulinoma is simply to consider it, particularly in relatively healthy-appearing persons who have fasting hypoglycemia associated with some degree of central nervous system dysfunction such as confusion or abnormal behavior. A delay in diagnosis can result in unnecessary treatment for psychomotor epilepsy or psychiatric disorders and may cause irreversible brain damage. In longstanding cases, obesity can result as a consequence of overeating to relieve symptoms.

The so-called **Whipple triad** is characteristic of hypoglycemia regardless of the cause. It consists of (1) a history of hypoglycemic symptoms, (2) an associated fasting blood glucose of 40 mg/dL or less, and (3) immediate recovery upon administration of glucose. The hypoglycemic symptoms in insulinoma often develop in the early morning or after missing a meal. Occasionally, they occur after exercise. They typically begin with evidence of central nervous system glucose lack and can include blurred vision or diplopia, headache, feelings of detachment, slurred speech, and weakness. Personality and mental changes vary from anxiety to psychotic behavior, and neurologic deterioration can result in convulsions or coma. Sweating and palpitations may not occur.

Hypoglycemic unawareness is very common in patients with insulinoma. They adapt to chronic hypoglycemia by increasing their efficiency in transporting glucose across the blood-brain barrier, which masks awareness that their blood glucose is approaching critically low levels. Counterregulatory hormonal responses as well as neurogenic symptoms such as tremor, sweating, and palpitations are therefore blunted during hypoglycemia. If lack of these warning symptoms prevents recognition of the need to eat to correct the problem, patients can lapse into severe hypoglycemic coma. However, symptoms and normal hormone responses during experimental insulin-induced hypoglycemia have been shown to be restored after successful surgical removal of the insulinoma. Presumably with return of euglycemia, adaptive effects on glucose transport into the brain are corrected, and thresholds of counterregulatory responses and neurogenic autonomic symptoms are therefore restored to normal.

Laboratory Findings

B cell adenomas do not reduce secretion in the presence of hypoglycemia, and the critical diagnostic test is to demonstrate inappropriately elevated serum insulin levels at a time when hypoglycemia is present. A reliable serum insulin level (radioimmunoassay) of 6 microunit/mL or more in the presence of blood glucose values below 40 mg/dL is diagnostic of inappropriate hyperinsulinism. Immunochemiluminometric assays (ICMA) have sensitivities of less than 1 microunit/mL, and with these assays, the cutoffs for insulinomas is insulin level 3 microunit/mL or higher. Other causes of hyperinsulinemic hypoglycemia must be considered, including factitious administration of insulin or sulfonylureas. Factitious use of insulin will result in suppression of endogenous insulin secretion and a low C-peptide levels. An elevated circulating proinsulin level in the presence of fasting hypoglycemia is characteristic of most B cell adenomas and does not occur in factitious hyperinsulinism. Thus, C-peptide and proinsulin levels (by ICMA) of > 200 pmol/L and > 5 pmol/L, respectively, are characteristic of insulinomas.

In patients with epigastric distress, a history of renal calculi, or menstrual or erectile dysfunction, a serum calcium, gastrin, or prolactin level may be useful in screening for MEN 1 associated with insulinoma.

Diagnostic Tests

Prolonged fasting

Prolonged fasting under hospital supervision until hypoglycemia is documented is probably the most dependable means of establishing the diagnosis, especially in men. In 30% of patients with insulinoma, the blood glucose levels often drop below 40 mg/dL after an overnight fast, but some patients require up to 72 hours to develop symptomatic hypoglycemia. However, the term

"72-hour fast" is actually a misnomer in most cases since the fast should be immediately terminated as soon as symptoms appear and laboratory confirmation of hypoglycemia is available. In normal male subjects, the blood glucose does not fall below 55–60 mg/dL during a 3-day fast. In contrast, in normal premenopausal women who have fasted for only 24 hours, the plasma glucose may fall normally to such an extent that it can reach values as low as 35 mg/dL. In these cases, however, the women are not symptomatic, presumably owing to the development of sufficient ketonemia to supply energy needs to the brain. Insulinoma patients, on the other hand, become symptomatic when plasma glucose drops to subnormal levels, since inappropriate insulin secretion restricts ketone formation. Moreover, the demonstration of a nonsuppressed insulin level 6 microunit/mL using a RIA assay (> 3 microunit/mL using an ICMA assay) in the presence of hypoglycemia suggests the diagnosis of insulinoma. If hypoglycemia does not develop in a male patient after fasting for up to 72 hours—and particularly when this prolonged fast is terminated with a period of moderate exercise—insulinoma must be considered an unlikely diagnosis. A suggested protocol for the supervised fast is shown in Table 27–15.

Table 27–15. Suggested hospital protocol for supervised fast in diagnosis of insulinoma.

(1) Obtain baseline serum glucose, insulin, proinsulin, and C-peptide measurements at onset of fast and place intravenous cannula.
(2) Permit only calorie-free and caffeine-free fluids and encourage supervised activity (such as walking).
(3) Measure urine for ketones at the beginning and every 12 hours and at the end of fast.
(4) Obtain capillary glucose measurements with a reflectance meter every 4 hours until values < 60 mg/dL are obtained. Then increase the frequency of fingersticks to each hour, and when capillary glucose value is < 49 mg/dL send a venous blood sample to the laboratory for serum glucose, insulin, proinsulin, and C-peptide measurements. Check frequently for manifestations of neuroglycopenia.
(5) If symptoms of hypoglycemia occur or if a laboratory value of serum glucose is < 45 mg/dL, or if 72 hours have elapsed then conclude the fast with a final blood sample for serum glucose, insulin, proinsulin, C-peptide, -hydroxybutyrate and sulfonylurea measurements. Then give oral fast-acting carbohydrate followed by a meal. If the patient is confused or unable to take oral agents, then administer 50 mL of 50% dextrose intravenously over 3 to 5 minutes. Do not conclude a fast based simply on a capillary blood glucose

measurement—wait for the laboratory glucose value—unless the patient is very symptomatic and it would be dangerous to wait.

Stimulation tests

Stimulation with pancreatic B cell secretagogues such as tolbutamide, glucagon, or leucine is generally not needed in most cases if basal insulin is found to be nonsuppressible and therefore inappropriately elevated during fasting hypoglycemia.

Intravenous glucagon (1 mg over 1 minute) can be useful in patients with "borderline" fasting inappropriate hyperinsulinism. A serum insulin rise above baseline of 200 microunit/mL or more at 5 and 10 minutes strongly suggests insulinoma, although poorly differentiated tumors may not respond. Glucagon has the advantage over tolbutamide of correcting rather than provoking hypoglycemia during stimulation testing and is diagnostic in 60–70% of patients with insulinoma. False-negative results can occur if the tumor is poorly differentiated and agranular.

Preoperative Localization of B Cell Tumors

After the diagnosis of insulinoma has been unequivocally made by clinical and laboratory findings, studies to localize the tumor should be initiated. The focus of attention should be directed to the pancreas since that is where virtually all insulinomas originate.

A spiral CT angiography of the pancreas should be performed to rule out a large tumor of the pancreas or hepatic metastases from a malignant islet cell tumor. Endoscopic ultrasonographic examination of the pancreas can also be helpful in identifying the pancreatic lesions. Because of the small size of these tumors (averaging 1.5 cm in diameter in one large series), imaging studies do not necessarily identify all the tumors. Patients who do not have an obvious tumor on imaging (but have a definite biochemical diagnosis) should undergo selective calcium-stimulated angiography. In this test, angiography is combined with injections of calcium gluconate into the gastroduodenal, splenic, and superior mesenteric arteries and insulin levels are measured in the hepatic vein effluent. Calcium stimulates insulin release from insulinomas but not normal islets, and so a step-up of insulin levels regionalizes the hyperinsulinism to the head of the pancreas for the gastroduodenal artery, to the uncinate process for the superior mesenteric artery, and to the body and tail of the pancreas for the splenic artery. This technique may also provide data that are particularly helpful when multiple insulinomas are suspected (MEN 1) and it has become a major tool in confirming the diagnosis of diffuse islet hyperplasia in the recently described noninsulinoma pancreatogenous hypoglycemia syndrome (NIPHS) (see below). Since diazoxide might interfere with this test, it should be discontinued for at least 48–72 hours before sampling. An infusion of dextrose may be required, therefore, and patients should be closely monitored during the procedure to avoid hypoglycemia (as well as hyperglycemia, which could affect insulin gradients). These studies combined with careful intraoperative ultrasonography and palpation by a surgeon experienced in insulinoma surgery identifies up to 98% of tumors.

Treatment

Surgical Measures

It is imperative that the surgeon be convinced that the diagnosis of insulinoma has been unequivocally made by clinical and laboratory findings. Only then should surgery be considered, as there is no justification for exploratory operation—just as there is none for the use of current localization techniques as a preoperative diagnostic tool. Resection by a surgeon with previous experience in removing pancreatic B cell tumors is the treatment of choice. In patients with a single benign adenoma 90–95% have a successful cure at the first surgical attempt when intraoperative ultrasound is used by a skilled surgeon. Blood glucose should be monitored throughout surgery, and 10% dextrose in water should be infused at a rate of 100 mL/h or faster. In cases where the diagnosis has been established but no adenoma is located after careful palpation and use of intraoperative ultrasound, it is no longer advisable to blindly resect the body and tail of the pancreas, since a nonpalpable tumor missed by ultrasound is most likely embedded within the fleshy head of the pancreas that is left behind with subtotal resections. Most surgeons prefer to close the incision and schedule a selective arterial calcium stimulation with hepatic venous sampling to locate the tumor site prior to a repeat operation. Laparoscopy using ultrasound and enucleation has been successful with a single tumor of the body or tail of the pancreas, but open surgery remains necessary for tumors in the head of the pancreas.

Diet and Medical Therapy

In patients with inoperable functioning islet cell carcinoma and in approximately 5–10% of MEN 1 cases when subtotal removal of the pancreas has failed to produce cure, reliance on frequent feedings is necessary. Since most tumors are not responsive to glucose, carbohydrate feedings every 2–3 hours are usually effective in preventing hypoglycemia, although obesity may become a problem. Diazoxide, 300–600 mg (or 3 mg to 8 mg/kg; 50 mg/mL oral suspension) daily orally in two or three divided doses, is the treatment of choice. Hydrochlorothiazide, 25–50 mg daily, should also be prescribed to counteract the sodium retention and edema secondary to diazoxide therapy as well as to potentiate its hyperglycemic effect. If patients are unable to tolerate diazoxide because of gastrointestinal upset, hirsutism, or edema, the calcium channel blocker verapamil may be beneficial in view of its inhibitory effect on insulin release from insulinoma cells. Octreotide, a potent long-acting synthetic octapeptide analog of somatostatin, has been used to inhibit release of hormones from a number of endocrine tumors. A dose of 50 mcg of octreotide injected subcutaneously twice daily has been tried in cases where surgery failed to remove the source of hyperinsulinism. However, its effectiveness is limited since its affinity for somatostatin receptors of the pancreatic B cell is very much less than for those of the anterior pituitary somatotrophs for which it was originally designed as treatment for acromegaly. When hypoglycemia persists after attempted surgical removal of the insulinoma and if diazoxide or verapamil is poorly tolerated or ineffective, multiple small feedings may be the only recourse until more selective somatostatin receptor agonists are available. Streptozocin can decrease insulin secretion in islet cell carcinomas, and effective doses have been delivered via selective arterial catheter so that the undue renal toxicity that characterized early experience is less of a problem.

Prognosis

When insulinoma is diagnosed early and cured surgically, complete recovery is likely, although brain damage following prolonged severe hypoglycemia is not reversible. A significant increase in survival rate has been shown in streptozocin-treated patients with islet cell carcinoma, with reduction in tumor mass as well as decreased hyperinsulinism.

Persistent Islet Hyperplasia (Noninsulinoma Pancreatogenous Hypoglycemia Syndrome)

In a very small number of patients with organic hyperinsulinism, islet hyperplasia rather than an adenoma is present. These patients typically have documented hyperinsulinemic hypoglycemia after meals but not with fasting up to 72 hours. The patients have a positive response to calcium-stimulated angiography. A gradient-guided partial pancreatectomy leads to clinical remission, and the pathology of the pancreas shows evidence of islet hyperplasia and nesidioblastosis. These patients do not have mutations in the *Kir 6.2* and *SUR1* genes, which has been reported in children with familial hyperinsulinemic hypoglycemia.

Hypoglycemia Due to Extrapancreatic Tumors

These rare causes of hypoglycemia include mesenchymal tumors such as retroperitoneal sarcomas, hepatocellular carcinomas, adrenocortical carcinomas, and miscellaneous epithelial-type tumors. The tumors are frequently large and readily palpated or visualized on CT scans or MRI.

The expression and release of an incompletely processed insulin-like growth factor-2 (IGF-2) has provided the best explanation for the clinical manifestations of hypoglycemia in these cases. A larger immature form of the IGF-2 molecule is released which binds to a carrier protein but not to an acid-labile component of serum which inactivates normal IGF-2. This immature IGF-2 complex therefore remains active and binds to insulin receptors in muscle to promote glucose transport and to insulin receptors in liver and kidney to reduce glucose output. It also binds to receptors for IGF-1 in the pancreatic B cell to inhibit insulin secretion. Serum levels of IGF-2 may be increased but often are "normal" in quantity, despite the presence of the immature, higher-molecular-weight form of IGF-2, which can only be detected by special laboratory techniques. Laboratory diagnosis depends on documenting fasting hypoglycemia associated with undetectable serum insulin levels.

The prognosis for these tumors is generally poor, and surgical removal should be attempted when feasible. Dietary management of the hypoglycemia is the mainstay of medical treatment, since diazoxide is usually ineffective.

Postprandial Hypoglycemia (Reactive Hypoglycemia)

Postgastrectomy Alimentary Hypoglycemia

Reactive hypoglycemia following gastrectomy is a consequence of hyperinsulinism resulting from rapid gastric emptying of ingested food. Symptoms result from adrenergic hyperactivity in response to the hypoglycemia. Treatment consists of more frequent feedings with smaller portions of less rapidly assimilated carbohydrate combined with more slowly absorbed fat and protein. Cases of hypoglycemia have been reported in patients who have undergone Roux-en-Y gastric bypass surgery for the treatment of obesity. The hypoglycemia occurs after meals and can be severe. There have been case reports of islet hyperplasia but this is probably uncommon; other studies report normal islet pathology.

Functional Alimentary Hypoglycemia

This syndrome is classified as functional when no postsurgical explanation exists for the presence of early alimentary type reactive hypoglycemia. It is most often associated with chronic fatigue, anxiety, irritability, weakness, poor concentration, decreased libido, headaches, hunger after meals, and tremulousness. However, most patients with these symptoms do not have hypoglycemia after a mixed meal. (See Chronic Fatigue Syndrome in Chapter 2: Common Symptoms).

Indiscriminate use and overinterpretation of glucose tolerance tests have led to an unfortunate tendency to overdiagnose functional hypoglycemia. As many as one-third or more of normal subjects have blood glucose levels as low as 40–50 mg/dL with or without symptoms during a 4-hour glucose tolerance test. Accordingly, to increase diagnostic reliability, hypoglycemia should preferably be documented during a spontaneous symptomatic episode accompanying routine daily activity, with clinical improvement following feeding. Oral glucose tolerance tests are overly sensitive and mixed meals are relatively insensitive in detecting postprandial reactive hypoglycemia. It has been shown that a high-carbohydrate breakfast has proved useful in differentiating persons with postprandial reactive hypoglycemia from normal controls. The test resulted in reactive hypoglycemia to levels below 59 mg/dL in 47% of 38 subjects, in contrast to only 2.2% of the 43 controls. This test was found to be much more sensitive than a standard mixed meal, which was also given to these two groups.

In patients with documented postprandial hypoglycemia on a functional basis, there is no harm and occasional benefit in reducing the proportion of carbohydrate in the diet while increasing the frequency and reducing the size of meals. Acarbose has also been reported to provide symptomatic relief and can be tried if dietary manipulations alone are ineffective.

Late Hypoglycemia (Occult Diabetes)

This condition is characterized by a delay in early insulin release from pancreatic B cells, resulting in initial exaggeration of hyperglycemia during a glucose tolerance test. In response to this hyperglycemia, an exaggerated insulin release produces a late hypoglycemia 4–5 hours after ingestion of glucose. These patients are usually quite different from those with early hypoglycemia occurring 2–3 hours after glucose ingestion, often being obese and frequently having a family history of diabetes mellitus.

In obese patients, treatment is directed at weight reduction to achieve ideal weight. Like all patients with postprandial hypoglycemia, regardless of cause, these patients often respond to reduced carbohydrate intake with multiple, spaced, small feedings. They should be considered potential diabetics and advised to have periodic medical evaluations.

Service GJ et al. Hyperinsulinemic hypoglycemia with nesidioblastosis after gastric-bypass surgery. N Engl J Med. 2005 Jul 21;353(3):249–54. [PMID: 16034010]

Alcohol-Related Hypoglycemia

Fasting Hypoglycemia after Ethanol

During the postabsorptive state, normal plasma glucose is maintained by hepatic glucose output derived from both glycogenolysis and gluconeogenesis. With prolonged starvation, glycogen reserves become depleted within 18–24 hours and hepatic glucose output becomes totally dependent on gluconeogenesis. Under these circumstances, a blood concentration of ethanol as low as

45 mg/dL can induce profound hypoglycemia by blocking gluconeogenesis. Neuroglycopenia in a patient whose breath smells of alcohol may be mistaken for alcoholic stupor. Prevention consists of adequate food intake during ethanol ingestion. Therapy consists of glucose administration to replenish glycogen stores until gluconeogenesis resumes.

Postethanol Reactive Hypoglycemia

When sugar-containing soft drinks are used as mixers to dilute alcohol in beverages (gin and tonic, rum and cola), there seems to be a greater insulin release than when the soft drink alone is ingested and a tendency for more of a late hypoglycemic overswing to occur 3–4 hours later. Prevention would consist of avoiding sugar mixers while ingesting alcohol and ensuring supplementary food intake to provide sustained absorption.

van de Wiel A. Diabetes mellitus and alcohol. Diabetes Metab Res Rev. 2004 Jul–Aug;20(4):263–7. [PMID: 15250029]

Factitious Hypoglycemia

Factitious hypoglycemia may be difficult to document. A suspicion of self-induced hypoglycemia is supported when the patient is associated with the health professions or has access to insulin or sulfonylurea drugs taken by a diabetic member of the family. The triad of hypoglycemia, high immunoreactive insulin, and suppressed plasma C peptide immunoreactivity is pathognomonic of exogenous insulin administration. Demonstration of circulating insulin antibodies supports this diagnosis in suspected cases. When sulfonylureas, repaglinide and nateglinide are suspected as a cause of factitious hypoglycemia, a plasma level of these drugs to detect their presence may be required to distinguish laboratory findings from those of insulinoma.

Immunopathologic Hypoglycemia

This rare cause of hypoglycemia, documented in isolated case reports, may occur as two distinct disorders: one associated with spontaneous development of circulating anti-insulin antibodies and another associated with antibodies to insulin receptors, in which the antibodies apparently have agonist capabilities. This latter disorder is extremely rare, having been documented in no more than five cases. However, development of anti-insulin antibodies has been reported in over 200 patients most of whom were being treated with methimazole for thyrotoxicosis. In Western countries, 23 cases have been reported and include patients with a lupus-like syndrome or with various paraproteinemias. The hypoglycemia occurs 3–4 hours after meals following an initial postprandial hyperglycemic phase that is due to the antibodies interfering with the exit of insulin from the plasma to reach its target tissues. Later, after most of the meal is absorbed, inappropriate high levels of insulin dissociate from this antibody-bound compartment, resulting in hypoglycemia. Insulin levels in excess of 1000 pmol/L are observed at time of hypoglycemia, and these persons have high titers of insulin autoantibodies.

Drug-Induced Hypoglycemia

A number of drugs apart from the sulfonylureas can occasionally cause hypoglycemia, especially when ingested in large amounts. These include quinine, quinidine, disopyramide, and salicylates. ACE inhibitors, when taken with antidiabetic drugs, can cause hypoglycemia possibly by improving insulin sensitivity. Recently, it has been reported that the use of gatifloxacin (an antibiotic that is no longer available in the United States) in diabetic patients is associated with serious hypoglycemic and hyperglycemic reactions.

Ten to 20 percent of patients receiving pentamidine for *Pneumocystis jiroveci* pneumonia develop symptomatic hypoglycemia, particularly when the drug is administered intravenously. This apparently is due to lytic destruction of pancreatic B cells, causing acute hyperinsulinemia and hypoglycemia. It is later followed by insulinopenia and hyperglycemia, which occasionally is persistent. Since other drugs have been found to be as effective in treating *Pneumocystis* pneumonia, pentamidine administration and its hypoglycemic sequelae are less frequently encountered.

Lipid Disorders: Introduction

For patients with known cardiovascular disease (secondary prevention), cholesterol lowering leads to a consistent reduction in total mortality and recurrent cardiovascular events in men and women and in middle-aged and older patients. Among patients without cardiovascular disease (primary prevention), the data are less conclusive, with rates of cardiovascular events, heart disease mortality, and all-cause mortality differing among studies. Nonetheless, treatment algorithms have been designed to assist clinicians in selecting patients for cholesterol-lowering therapy based on their lipid levels and their overall risk of developing cardiovascular disease.

See Related Guideline from *CURRENT Practice Guidelines in Primary Care 2009*

Lipids & Lipoproteins

The two main lipids in blood are cholesterol and triglyceride. They are carried in lipoproteins, globular particles that also contain proteins known as apoproteins. Cholesterol is an essential element of all animal cell membranes and forms the backbone of steroid hormones and bile acids; triglycerides are important in transferring energy from food into cells. Why lipids are deposited into the walls of large and medium-sized arteries—an event with potentially lethal consequences—is not known.

Lipoproteins are usually classified on the basis of density, which is determined by the amounts of triglyceride (which makes them less dense) and apoproteins (which makes them more dense). The least dense particles, known as chylomicrons, are normally found in the blood only after fat-containing foods have been eaten. They rise as a creamy layer when nonfasting serum is allowed to stand. The other lipoproteins are suspended in serum and must be separated using a centrifuge. The densest (and smallest) family of particles consists mainly of apoproteins and cholesterol and is called high-density lipoproteins (HDL). Somewhat less dense are the low-density lipoproteins (LDL). Least dense are the large, very-low-density lipoproteins (VLDL), consisting mainly of triglyceride. In fasting serum, most of the cholesterol is carried on LDL particles and is therefore referred to as LDL cholesterol; most of the triglyceride is found in VLDL particles. Specific apoproteins are associated with each lipoprotein class.

Chylomicrons are made in the gut and travel via the portal vein into the liver and via the thoracic duct into the circulation (see illustration). They are normally completely metabolized, transferring energy from food into muscle and fat cells. The liver manufactures VLDL particles from its own stores of fat and carbohydrate. VLDL particles transfer triglyceride to cells; after losing enough, they eventually become LDL particles, which provide cholesterol for cellular needs. Excess LDL particles are taken up by the liver, and the cholesterol they contain is then excreted into the bile. HDL particles are made in the liver and intestine and appear to facilitate the transfer of apoproteins among lipoproteins. They also participate in reverse cholesterol transport, either by transferring cholesterol into other lipoproteins or directly into the liver.

Lipoproteins & Atherogenesis

The plaques in the arterial walls of patients with atherosclerosis contain large amounts of cholesterol. The higher the level of low-density lipoproteins (LDL) cholesterol, the greater the risk of atherosclerotic heart disease; conversely, the higher the high-density lipoproteins (HDL) cholesterol, the lower the risk of coronary heart disease (CHD). This is true in men and women, in different racial and ethnic groups, and at all ages up to age 75 years. Because most cholesterol in serum is LDL, high total cholesterol levels are also associated with an increased risk of CHD. Middle-aged men whose serum cholesterol levels are in the highest quintile for age (above about 230 mg/dL) have a risk of coronary death before age 65 years of about 10%; men in the lowest quintile (below about 170 mg/dL) have a 3% risk. Death from CHD before age 65 years is less common in women, with equivalent risks one-third those of men. In men, each 10-mg/dL increase in cholesterol (or LDL cholesterol) increases the risk of CHD by about 10%; each 5-mg/dL increase in HDL reduces the risk by about 10%. The effect of HDL cholesterol is greater in women, whereas the effects of total and LDL cholesterol are smaller.

The exact mechanism by which LDL particles result in the formation of atherosclerotic plaques—or the means whereby HDL particles protect against their formation—is not known. The model of LDL carrying cholesterol into the walls of arteries with HDL removing it is simple but not established. The natural oxidation of LDL particles may be particularly atherogenic. Receptors on the surface of macrophages within atherosclerotic plaques bind and accumulate oxidized LDL. The formation of antibodies to oxidized LDL may also be important in plaque formation. The size of the LDL molecule may also influence atherogenesis; at the same LDL concentrations, individuals with large numbers of smaller particles appear to be at higher risk for CHD.

The relationship of VLDL cholesterol to atherogenesis is less certain. The number, size, or subtype of VLDL particles—in addition to the total amount in serum—may be important. In addition, HDL and VLDL levels are inversely related. Patients with a high VLDL level are likely to have a low HDL level and thus be at increased risk for CHD for that reason alone.

There are several genetic disorders that provide insight into the pathogenesis of lipid-related diseases. **Familial hypercholesterolemia**, rare in the homozygous state (about one per million) is a condition in which the cell-surface receptors for the LDL molecule are absent or defective, resulting in unregulated synthesis of LDL. Patients with two abnormal genes (homozygotes) have extremely high levels—up to eight times normal—and present with atherosclerotic disease in childhood. Homozygotes may require liver transplantation to correct their severe lipid abnormalities. Those with one defective gene (heterozygotes) have LDL concentrations twice normal; persons with this condition may develop CHD in their 30s or 40s.

Another rare condition is caused by an abnormality of lipoprotein lipase, the enzyme that enables peripheral tissues to take up triglyceride from chylomicrons and very-low-density lipoproteins (VLDL) particles. Patients with this condition, one cause of **familial hyperchylomicronemia,** have marked hypertriglyceridemia with recurrent pancreatitis and hepatosplenomegaly in childhood.

Numerous other genetic abnormalities of lipid metabolism are named for the abnormality noted when serum is electrophoresed (eg, dysbetalipoproteinemia) or from combinations of lipid abnormalities in families (eg, familial combined hyperlipidemia). Thus, family members of patients with severe lipid disorders are appropriately studied. Other patients have abnormalities in the production of apoproteins, such as increased apoprotein B and its affiliated lipoproteins, LDL and VLDL; reduced apoprotein AII and its affiliated particle; or excess lipoprotein(a). Other mutations occur in lipoprotein lipase and in the gene encoding for cholesterol efflux regulatory protein.

When to Refer

- Known genetic lipid disorders.
- Striking family history of hyperlipidemia or premature atherosclerosis.
- Extremely high serum LDL cholesterol or triglyceride, or extremely low serum HDL cholesterol.

Lipid Fractions & the Risk of Coronary Heart Disease

In fasting serum, cholesterol is carried primarily on three different lipoproteins—the VLDL, LDL, and HDL molecules. Total cholesterol equals the sum of these three components:

Most clinical laboratories measure the total cholesterol, the total triglycerides, and the amount of cholesterol found in the HDL fraction, which is easily precipitated from serum. Most triglyceride is found in VLDL particles, which contain five times as much triglyceride by weight as cholesterol. The amount of cholesterol found in the VLDL fraction can be estimated by dividing the triglyceride by 5:

Because the triglyceride level is used as a proxy for the amount of VLDL, this formula works only in fasting samples and when the triglyceride level is less than 400 mg/dL. At higher triglyceride levels, LDL and VLDL cholesterol levels can be determined after ultracentrifugation or by direct chemical measurement.

he total cholesterol is reasonably stable over time; however, measurements of HDL and especially triglycerides may vary considerably because of analytic error in the laboratory and biologic variation in a patient's lipid level. Thus, the LDL should always be estimated as the mean of at least two determinations; if those two estimates differ by more than 10%, a third lipid profile is obtained. The LDL is estimated as follows:

When using SI units, the formula becomes:

Understanding the relationships of the different lipid fractions leads to a more accurate understanding of a patient's lipid-related coronary risk than the total cholesterol. Two persons with the same total cholesterol of 275 mg/dL may have very different lipid profiles. One may have an HDL cholesterol of 110 mg/dL with a triglyceride of 150 mg/dL, giving an estimated LDL cholesterol of 135 mg/dL; the other may have an HDL cholesterol of 25 mg/dL with a triglyceride of 200 mg/dL and an LDL cholesterol of 210 mg/dL. The second would have more than a tenfold higher CHD risk than the first, assuming no differences in other factors. Because of high HDL cholesterol levels in women, many with apparently high total cholesterol levels have favorable lipid profiles. Thus, evaluation of the lipid fractions is essential before therapy is initiated.

Some authorities use the ratio of the total to HDL cholesterol as an indicator of lipid-related coronary risk: the lower this ratio is, the better. (In the example above, the first person would have a ratio of 275 ÷ 110 = 2.5, while the second would have a much less favorable ratio of 275 ÷ 25 = 11.) Although ratios are useful predictors within populations of patients, they may obscure important information in individual patients. (A total cholesterol of 300 mg/dL and an HDL of 60 mg/dL result in the same ratio of 5 as a total cholesterol of 150 mg/dL with an HDL of 30 mg/dL.) Moreover, the total cholesterol-to-HDL cholesterol ratio will magnify the importance of variations in HDL measurement.

There is no true "normal" range for serum lipids. In Western populations, cholesterol values are about 20% higher than in Asian populations and exceed 300 mg/dL in nearly 5% of adults. About 10% of adults have LDL cholesterol levels above 200 mg/dL. Total and LDL cholesterol levels tend to rise with age in persons who are otherwise in good health.

Declines are seen in acute illness, and lipid studies in such patients are of little value with the exception of the serum triglyceride level in a patient with pancreatitis. Cholesterol levels (even when expressed as an age-matched percentile rank, such as the highest 20%) do not remain constant over time, especially from childhood through adolescence and young adulthood. Thus, children and young adults with relatively high cholesterol may have lower levels later in life, whereas those with low cholesterol may show increases.

Therapeutic Effects of Lowering Cholesterol

Reducing cholesterol levels in healthy middle-aged men without CHD (primary prevention) reduces their risk in proportion to the reduction in LDL cholesterol and the increase in HDL cholesterol. Treated patients have statistically significant and clinically important reductions in the rates of myocardial infarctions, new cases of angina, and need for coronary artery bypass procedures.

The West of Scotland Study showed a 31% decrease in myocardial infarctions in middle-aged men treated with pravastatin compared with placebo. The Air Force/Texas Coronary Atherosclerosis Prevention Study (AFCAPS/TexCAPS) study showed similar results with lovastatin. As with any primary prevention interventions, large numbers of healthy patients need to be treated to prevent a single event. The numbers of patients needed to treat (NNT) to prevent a nonfatal myocardial infarction or a coronary artery disease death in these two studies were 46 and 50, respectively. The Anglo-Scandinavian Cardiac Outcomes Trial (ASCOT) study of atorvastatin in subjects with hypertension and other risk factors but without CHD also demonstrated a convincing 36% reduction in CHD events. The Justification for the Use of Statins in Prevention: an Intervention Trial Evaluating Rosuvastatin (JUPITER) showed a 44% reduction in a combined end point of myocardial infarction, stroke, revascularization, hospitalization for unstable angina, or death from cardiovascular causes. The NNT for 1 year to prevent one event was 169.

Primary prevention studies have found a less consistent effect on total mortality. The West of Scotland study found a 20% decrease in total mortality, tending toward statistical significance. The AFCAPS/TexCAPS study with lovastatin showed no difference in total mortality. The Antihypertensive and Lipid-Lowering Treatment to

Prevent Heart Attack Trial (ALLHAT-LLT) also showed no reduction either in all-cause mortality or in CHD events when pravastatin was compared with usual care. Subjects treated with atorvastatin in the ASCOT study had a 13% reduction in mortality, but the result was not statistically significant. This study, however, was stopped early due to the marked reduction in CHD events. The JUPITER trial demonstrated a statistically significant 20% reduction in death from any cause. The NNT for 1 year was 400.

In patients with CHD, the benefits of cholesterol lowering are clearer. Major studies with statins have shown significant reductions in cardiovascular events, cardiovascular deaths, and all-cause mortality in men and women with coronary artery disease. The NNT to prevent a nonfatal myocardial infarction or a coronary artery disease death in these three studies were between 12 and 34. Aggressive cholesterol lowering with these agents causes regression of atherosclerotic plaques in some patients, reduces the progression of atherosclerosis in saphenous vein grafts, and can slow or reverse carotid artery atherosclerosis. Meta-analysis suggests that this latter effect results in a significant decrease in strokes. Results with other classes of medications have been less consistent. For example, gemfibrozil treatment subjects had fewer cardiovascular events, but there was no benefit in all-cause mortality when compared with placebo.

The disparities in results between primary and secondary prevention studies highlight several important points. The benefits and adverse effects of cholesterol lowering may be specific to each type of drug; the clinician cannot assume that the effects will generalize to other classes of medication. Second, the net benefits from cholesterol lowering depend on the underlying risk of CHD and of other disease. In patients with atherosclerosis, morbidity and mortality rates associated with CHD are high, and measures that reduce it are more likely to be beneficial even if they have no effect—or even slightly harmful effects—on other diseases.

Secondary Conditions That Affect Lipid Metabolism

Several factors, including drugs, can influence serum lipids (Table 28–1). These are important for two reasons: Abnormal lipid levels (or changes in lipid levels) may be the presenting sign of some of these conditions, and correction of the underlying condition may obviate the need to treat an apparent lipid disorder. Diabetes and alcohol use, in particular, are commonly associated with high triglyceride levels that decline with improvements in glycemic control or reduction in alcohol use, respectively. Thus, secondary causes of high blood lipids should be considered in each patient with a lipid disorder before lipid-lowering therapy is started. In most instances, special testing is not needed: a history and physical examination are sufficient. However, screening for hypothyroidism in patients with hyperlipidemia is cost effective.

Table 28–1. Secondary causes of lipid abnormalities.

Cause	**Associated Lipid Abnormality**
Obesity	Increased triglycerides, decreased HDL cholesterol
Sedentary lifestyle	Decreased HDL cholesterol
Diabetes mellitus	Increased triglycerides, increased total cholesterol

Alcohol use	Increased triglycerides, increased HDL cholesterol
Hypothyroidism	Increased total cholesterol
Hyperthyroidism	Decreased total cholesterol
Nephrotic syndrome	Increased total cholesterol
Chronic kidney disease	Increased total cholesterol, increased triglycerides
Liver disease (cirrhosis)	Decreased total cholesterol
Obstructive liver disease	Increased total cholesterol
Malignancy	Decreased total cholesterol
Cushing's disease (or corticosteroid use)	Increased total cholesterol
Oral contraceptives	Increased triglycerides, increased total cholesterol
Diuretics [1]	Increased total cholesterol, increased triglycerides
-Blockers[1,2]	Increased total cholesterol, decreased HDL

[1] Short-term effects only.

[2] -Blockers with intrinsic sympathomimetic activity, such as pindolol and acebutolol, do not affect lipid levels.

Clinical Presentations

Most patients with high cholesterol levels have no specific symptoms or signs. The vast majority of patients with lipid abnormalities are detected by the laboratory, either as part of the workup of a patient with cardiovascular disease or as part of a preventive screening strategy. Extremely high levels of chylomicrons or VLDL particles (triglyceride level above 1000 mg/dL) result in the formation of **eruptive xanthomas** (Plate 93) (red-yellow papules, especially on the buttocks (see photograph)). High LDL concentrations result in **tendinous xanthomas** on certain tendons (Achilles, patella, back of the hand) (see photograph); (see photograph); (see photograph); (see photograph). Such xanthomas usually indicate one of the underlying genetic hyperlipidemias. **Lipemia retinalis** (cream-colored blood vessels in the fundus) is seen with extremely high triglyceride levels (above 2000 mg/dL) (see funduscopy).

Screening for High Blood Cholesterol

See Related Guideline from *CURRENT Practice Guidelines in Primary Care 2009*

All patients with CHD or CHD risk equivalents (other clinical forms of atherosclerosis such as peripheral artery disease, abdominal aortic aneurysm, and symptomatic carotid artery disease; patients with diabetes mellitus; and patients with multiple risk factors that confer a greater than 20% 10-year risk for developing CHD) should be screened for elevated lipids. The only exceptions are patients in whom lipid lowering is not indicated or desirable for other reasons. Patients who already have evidence of atherosclerosis are the group at highest risk of suffering additional manifestations in the near term and thus have the most to gain from reduction of blood lipids. Additional risk reduction measures for atherosclerosis are discussed in Chapter 10: Heart Disease; lipid lowering should be just one aspect of a program to reduce the progression and effects of the disease.

In patients with cardiovascular disease, a complete lipid profile (total cholesterol, HDL cholesterol, and triglyceride levels) after an overnight fast should be obtained as a screening test. Those whose estimated LDL cholesterol level is high should have at least one repeat measurement. Specific treatments for high LDL cholesterol levels are discussed below. The goal of therapy should be to reduce the LDL cholesterol to below 100 mg/dL or optimally to below 70 mg/dL. Evidence suggests that treatment with a statin is effective even if the starting LDL cholesterol is below 100 mg/dL. These data suggest that most patients with CHD or CHD risk equivalents should be treated with statin therapy.

The best screening and treatment strategy for adults who do not have atherosclerotic cardiovascular disease is less clear. Several algorithms have been developed to guide the clinician in treatment decisions, but management decisions are individualized based on the patient's risk.

Although the National Cholesterol Education Program (NCEP) recommends screening of all adults aged 20 years or older for high blood cholesterol, the United States Preventive Services Task Force (USPSTF) suggests beginning at age 35 years in men and age 45 years in women unless there are other risk factors for CHD. For men and women with an increased risk for CHD, however, screening should begin at age 20. Although there is no established interval for screening, screening can be repeated every 5 years for those with average or low risk and more often for those whose levels are close to therapeutic thresholds. This strategy focuses cholesterol screening on those at the greatest risk of coronary artery disease and increases the cost effectiveness of cholesterol screening.

Individuals without cardiovascular disease can then be stratified according to risk factors as defined by the NCEP. Those with two or more risk factors are considered to be at intermediate risk of coronary artery disease, and those with less than two are at low risk. These include age and gender (men aged 45 years or older, women aged 55 years or older), a family history of premature CHD (myocardial infarction or sudden cardiac death before age 55 years in a first-degree male relative or before age 65 years in a first-degree female relative), hypertension (whether treated or not), current cigarette smoking (10 or more cigarettes per day), and low HDL cholesterol (< 40 mg/dL). Because HDL cholesterol is protective against CHD, a risk factor is subtracted if the level is greater than 60 mg/dL. Patients with two or more risk factors are then further stratified by evaluating their 10-year risk of developing CHD using Framingham projections of 10-year risk (Table 28–2). Because risk factors alone are an imprecise measure of CHD risk, estimating the 10-year risk using Framingham data is helpful even in patients with one or no risk factors. Other measures may also be useful to further refine risk in selected patients. For example, high-sensitivity C-reactive protein (hs-CRP) may be useful in intermediate-risk patients if the decision to initiate medications might change based on the hs-CRP level.

Table 28–2. Framingham 10-year coronary heart disease risk projections. Calculate the number of points for each risk factor. Sum the total risk score and estimate the 10-year risk.[1]

[1] Reproduced, with permission, from Executive Summary of the Third Report of The National Cholesterol Education Program (NCEP) Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol In Adults (Adult Treatment Panel III). JAMA. 2001 May 16;285(19):2486–97. http://www.nhlbi.nih.gov/guidelines/cholesterol/index.htm.

Several strategies for obtaining the initial cholesterol measurement have been proposed, including (1) measuring total cholesterol alone, (2) measuring total cholesterol and HDL cholesterol, or (3) measuring LDL and HDL cholesterol. Each is acceptable, but treatment decisions are based on the LDL and HDL cholesterol levels. Measurement of the total cholesterol alone is the least expensive strategy and is adequate for low-risk individuals; those with total cholesterol greater than 200 mg/dL should then be reevaluated with a fasting LDL and HDL cholesterol measurement. Measurement of the total cholesterol and HDL cholesterol allows for better characterization of the risk factor profile but also requires reevaluation if the total cholesterol is greater than 200 mg/dL as recommended by the USPSTF. Initial measurement of the LDL and HDL cholesterol is least likely to lead to patient misinformation and misclassification and is the strategy recommended by the NCEP.

Treatment decisions are based on the LDL cholesterol, and the patient's risk factor profile (including the HDL cholesterol level) and estimated 10-year risk. Patients in the intermediate-risk group (two or more risk factors) are selected for diet therapy (therapeutic lifestyle changes) if LDL cholesterol is greater than 130 mg/dL. If the 10-year risk of CHD is < 10%, drug treatment is recommended if

LDL is > 160 mg/dL; if the 10-year CHD risk is between 10% and 20%, drug treatment is recommended if LDL is > 130 mg/dL. Low-risk individuals with one or no risk factors and estimated 10-year CHD risk less than 10% are selected for diet therapy if LDL cholesterol is greater than 160 mg/dL and for drug therapy if it is greater than 190 mg/dL (Table 28–3).

Table 28–3. LDL goals and treatment cutpoints: Recommendations of the NCEP Adult Treatment Panel III.

Risk Category	**LDL Goal (mg/dL)**	**LDL Level at Which to Initiate Lifestyle Changes (mg/dL)**	**LDL Level at Which to Consider Drug Therapy[1] (mg/dL)**
High risk: CHD[2] or CHD risk equivalents[3] (10-year risk > 20%)	< 100 (optional goal: < 70 mg/dL)[4]	100[5]	100[6] (< 100: consider drug options)[1]
Moderately high risk: 2+ risk	< 130[9]	130[5]	130 (100–

factors[7] (10-year risk 10% to 20%)[8]			129; consider drug options)[10]
Moderate risk: 2+ risk factors[7] (10-year risk < 10%)[8]	< 130	130	160
Low risk: 0–1 risk factors[11]	< 160	160	190 (160–189: LDL-lowering drug optional)

[1] When LDL-lowering drug therapy is used, it is advised that intensity of therapy be sufficient to achieve at least a 30–40% reduction in LDL cholesterol levels.

[2] CHD includes history of myocardial infarction, unstable angina, coronary artery procedures (angioplasty or bypass surgery), or evidence of clinically significant myocardial ischemia.

[3] CHD risk equivalents include clinical manifestations of noncoronary forms of atherosclerotic disease (peripheral arterial disease, abdominal aortic aneurysm, and carotid artery disease [transient ischemic attacks or stroke of

carotid origin with > 50% obstruction of a carotid artery]), diabetes mellitus, and 2 risk factors with 10-year risk for CHD > 20%.

[4] Very high risk favors the optional LDL cholesterol goal of < 70 mg/dL, or in patients with high triglycerides, non-high density lipoprotein (HDL) cholesterol < 100 mg/dL.

[5] Any person at high risk or moderately high risk who has lifestyle-related risk factors (eg, obesity, physical inactivity, elevated triglyceride, low HDL cholesterol, or metabolic syndrome) is a candidate for therapeutic lifestyle changes to modify these risk factors regardless of LDL cholesterol.

[6] If baseline LDL cholesterol is < 100 mg/dL, institution of an LDL-lowering drug is a therapeutic option on the basis of available clinical trial results. If a high-risk person has high triglycerides or low HDL cholesterol, combining a fibrate or nicotinic acid with an LDL-lowering drug can be considered.

[7] Risk factors include cigarette smoking, hypertension (blood pressure 140/90 mm Hg or on antihypertensive medication), low HDL cholesterol (< 40 mg/dL), family history of premature CHD (CHD in male first-degree relative < 55 years of age; CHD in female first-degree relative < 65 years of age), and age (men 45 years;

women 55 years).

[8] Electronic 10-year risk calculators are available at http://www.nhlbi.nih.gov/guidelines/cholesterol.

[9] Optional LDL cholesterol goal < 100 mg/dL.

[10] For moderately high-risk persons, when the LDL cholesterol level is 100–129 mg/dL at baseline or on lifestyle therapy, initiation of an LDL-lowering drug to achieve an LDL cholesterol level < 100 mg/dL is a therapeutic option on the basis of available clinical trial results.

[11] Almost all people with zero or one risk factor have a 10-year CHD risk < 10%, and 10-year risk assessment in these people is thus not necessary.

LDL, low-density lipoprotein; NCEP, National Cholesterol Education Program; CHD, coronary heart disease.

Screening in Women

The foregoing screening and treatment guidelines, based largely on LDL cholesterol levels, are designed for both men and women. Yet several observational studies suggest that a low HDL cholesterol is a more important risk factor for CHD in women than a high LDL cholesterol. Meta-analysis of studies including women with known heart disease, however, has found that medications that primarily lower LDL cholesterol do prevent recurrent myocardial infarctions in women. There is insufficient evidence to be certain of a similar effect from LDL-lowering therapy in women without evidence of CHD. Although most experts recommend application of the same primary prevention guidelines for women as for men, clinicians should be aware of the uncertainty in this area. Using estimates of 10-year CHD risk may be particularly helpful in women since a larger percentage of women than men will have estimated 10-year CHD risks below 10% per year and thus women are less likely to benefit from therapy unless their LDL cholesterol is extremely high (greater than 190 mg/dL).

Screening in Older Patients

Meta-analysis of evidence relating cholesterol to CHD in the elderly suggests that cholesterol is not a risk factor for CHD for persons over age 75 years. Clinical trials have rarely included such individuals. One exception is the Prospective Study of Pravastatin in the Elderly at Risk (PROSPER). In this study, elderly patients with cardiovascular disease (secondary prevention) benefited from statin therapy, whereas those without cardiovascular disease (primary prevention) did not. Although the NCEP recommends continuing treatment in the elderly, many clinicians will prefer to stop screening and treatment in patients age 75 years or older who do not have CHD. In patients age 75 years or older who have CHD, LDL-lowering therapy can be continued as recommended for younger patients with the disease. Decisions to discontinue therapy should be based on overall functional status and life expectancy, comorbidities, and patient preference and should be made in context with overall therapeutic goals and end-of-life decisions.

Treatment of High Low-Density Lipoprotein Cholesterol

Reduction of LDL cholesterol is just one part of a program to reduce the risk of cardiovascular disease. Other measures—including smoking cessation, hypertension control, and aspirin—are also of central importance. Less well studied but of potential value is raising the HDL cholesterol level. Quitting smoking reduces the effect of other cardiovascular risk factors (such as a high cholesterol level); it may also increase the HDL cholesterol level. Exercise (and weight loss) may reduce the LDL cholesterol and increase the HDL. Modest alcohol use (1–2 ounces a day) also raises HDL levels and appears to have a salutary effect on CHD rates.

Several new classes of medications are being actively tested to raise HDL cholesterol levels. One such class of these medications, the cholesteryl ester transfer protein inhibitors, raises HDL cholesterol levels. However, studies to date of one agent in this class, torcetrapib, have shown adverse effects on cardiovascular outcomes. The effects of reconstituted HDL infusions have also been studied but have shown only modest effects on indirect measures of atherosclerosis.

Diet Therapy

Studies of nonhospitalized adults have reported only modest cholesterol-lowering benefits of dietary therapy, typically in the range of a 5–10% decrease in LDL cholesterol, with even less in the long term. The effect of diet therapy, however, varies considerably among individuals, as some patients will have striking reductions in LDL cholesterol—up to a 25–30% decrease—whereas others will have clinically important increases. Thus, the results of diet therapy should be assessed about 4 weeks after initiation.

Cholesterol-lowering diets may also have a variable effect on lipid fractions. Diets very low in total fat or in saturated fat may lower HDL cholesterol as much as LDL cholesterol. It is not known how these diet-induced changes affect coronary risk.

Several nutritional approaches to diet therapy are available. Most Americans currently eat over 35% of calories as fat, of which 15% is saturated fat. Dietary cholesterol intake averages 400 mg/d. A cholesterol-lowering diet recommends reducing total fat to 25–30% and saturated fat to less than 7% of calories. Dietary cholesterol should be limited to less than 200 mg/d. These diets replace fat, particularly saturated fat, with carbohydrate. In most instances, this approach will also result in fewer total calories consumed and will facilitate weight loss in overweight patients. Other diet plans, including the Dean Ornish Diet, the Pritikin Diet, and most vegetarian diets, restrict fat even further. Low-fat, high-carbohydrate diets may, however, result in reductions in HDL cholesterol.

An alternative strategy is the "Mediterranean diet," which maintains total fat at approximately 35–40% of total calories but replaces saturated fat with monounsaturated fat such as that found in canola oil and in olives, peanuts, avocados, and their oils. This diet is equally effective at lowering LDL cholesterol but is less likely to lead to reductions in HDL cholesterol. Recent studies have demonstrated that this approach may also be associated with reductions in endothelial dysfunction, insulin resistance, and markers of vascular inflammation and may result in better resolution of the metabolic syndrome than traditional cholesterol-lowering diets.

Other dietary changes may also result in beneficial changes in blood lipids. Soluble fiber, such as that found in oat bran or psyllium, may reduce LDL cholesterol by 5–10%. Garlic, soy protein, vitamin C, pecans, and plant sterols may also result in reduction of LDL cholesterol. Because oxidation of LDL cholesterol is a potential initiating event in atherogenesis, diets rich in antioxidants, found primarily in fruits and vegetables, may be helpful (see Chapter 29: Nutritional Disorders). Studies have suggested that when all of these elements are combined into a single dietary prescription, the impact of diet on LDL cholesterol may approach that of statin medications, lowering LDL cholesterol by close to 30%.

Pharmacologic Therapy

All patients whose risk from CHD is considered high enough to warrant pharmacologic therapy of an elevated LDL cholesterol should be given aspirin prophylaxis at a dose of 81 mg/d unless there are contraindications such as aspirin sensitivity, bleeding diatheses, or active peptic ulcer disease. The benefit of aspirin in reducing the risk of CHD is equivalent to that of cholesterol lowering. Other CHD risk factors, such as hypertension and smoking, should also be controlled.

If the decision to treat a patient with an LDL-lowering drug is made, a goal for treatment is set. The National Cholesterol Education Program's Adult Treatment Panel III (NCEP ATP III) published revised, more intensive LDL treatment goals in 2004, and these guidelines remain the mainstay of clinical practice. For patients with CHD or CHD risk equivalents, the goal is LDL < 100 mg/dL, but for patients with very high risk, a goal of LDL < 70 mg/dL is a therapeutic option (see Table 28–3). This goal may also be appropriate for patients with very high risk who have a baseline LDL < 100 mg/dL. For patients with two or more risk factors and a 10-year CHD risk of 10–20%, the recommended goal is LDL < 130 mg/dL, but a goal of < 100 mg/dL is optional. For those with two or more risk factors and a 10-year CHD risk of < 10%, the goal is < 130 mg/dL. For those with zero or one risk factor, the goal is LDL < 160 mg/dL (see Table 28–3). In most instances, intensity of therapy should be sufficient to achieve a 30–40% reduction in LDL cholesterol.

Combinations of drugs may be necessary. Once the goal is reached, the lipid profile should be monitored periodically (every 6–12 months), with consideration given to periodic reductions in drug dose. Most lipid-lowering agents are expensive and may need to be given for decades. Thus, their cost effectiveness is low for some groups of patients, especially in primary prevention.

Niacin (Nicotinic Acid)

Niacin was the first lipid-lowering agent that was associated with a reduction in total mortality. Long-term follow-up of a secondary prevention trial of middle-aged men with previous myocardial infarction disclosed that about half of those who had been previously treated with niacin had died, compared with nearly 60% of the placebo group. This favorable effect on mortality was not seen during the trial itself, though there was a reduction in the incidence of recurrent coronary events.

Niacin reduces the production of VLDL particles, with secondary reduction in LDL and increases in HDL cholesterol levels. The average effect of full-dose niacin therapy, 3–4.5 g/d, is a 15–25% reduction in LDL cholesterol and a 25–35% increase in HDL cholesterol. Full doses are required to obtain the LDL effect, but the HDL effect is observed at lower doses, eg, 1 g/d. Niacin will also reduce triglycerides by half and will lower lipoprotein(a) (Lp[a]) levels and will increase plasma homocysteine levels. Thus, its effect on blood lipids and CHD risk is nearly optimal. Intolerance to niacin is common; only 50–60% of patients can take full doses. Niacin causes a prostaglandin-mediated flushing that patients may describe as "hot flashes" or pruritus and that can be decreased with aspirin (81–325 mg/d) or other nonsteroidal anti-inflammatory agents taken during the same day. Flushing may also be decreased by initiating niacin therapy with a very small dose, eg, 100 mg with the evening meal. The dose can be doubled each week until 1.5 g/d is tolerated. After rechecking blood lipids, the dose is increased and divided over three meals until the goal of 3–4.5 g/d is reached (eg, 1 g with each meal). Extended-release niacin is also available and is better tolerated by most patients. It is not known whether routine monitoring of liver enzymes results in early detection and thus reduced severity of this side effect. Niacin can also exacerbate gout and peptic ulcer disease. Although niacin may increase blood sugar in some patients, clinical trials have shown that niacin can be safely used in diabetics.

Bile Acid-Binding Resins

The bile acid-binding resins include cholestyramine, colesevelam, and colestipol. Treatment with these agents reduces the incidence of coronary events in middle-aged men by about 20%, with no significant effect on total mortality. The resins work by binding bile acids in the intestine. The resultant reduction in the enterohepatic circulation causes the liver to increase its production of bile acids, using hepatic cholesterol to do so. Thus, hepatic LDL receptor activity increases, with a decline in plasma LDL levels. The triglyceride level tends to increase slightly in some patients treated with bile acid-binding resins; they should be used with caution in those with elevated triglycerides and probably not at all in patients who have triglyceride levels above 500 mg/dL. The clinician can anticipate a reduction of 15–25% in the LDL cholesterol level, with insignificant effects on the HDL level.

The usual dose of cholestyramine is 12–36 g of resin per day in divided doses with meals, mixed in water or, more palatably, juice. Doses of colestipol are 20% higher (each packet contains 5 g of resin). The dose of colesevelam is 625 mg, 6–7 tablets per day.

These agents often cause gastrointestinal symptoms, such as constipation and gas. They may interfere with the absorption of fat-soluble vitamins (thereby complicating the management of patients receiving warfarin) and may bind other drugs in the intestine. Concurrent use of psyllium may ameliorate the gastrointestinal side effects.

Hydroxymethylglutaryl-Coenzyme A (HMG-CoA) Reductase Inhibitors (Statins)

The HMG-CoA reductase inhibitors include atorvastatin, fluvastatin, lovastatin, pravastatin, rosuvastatin, and simvastatin. These agents work by inhibiting the rate-limiting enzyme in the formation of cholesterol. They reduce myocardial infarctions and total mortality in secondary prevention, as well as in older middle-aged men free of CHD. A meta-analysis has demonstrated significant reduction in risk of stroke. Cholesterol synthesis in the liver is reduced, with a compensatory increase in hepatic LDL receptors (presumably so that the liver can take more of the cholesterol that it needs from the blood) and a reduction in the circulating LDL cholesterol level by up to 35%. There are also modest increases in HDL levels and decreases in triglyceride levels.

Oral doses are as follows: atorvastatin, 10–80 mg/d; fluvastatin, 20–40 mg/d; lovastatin, 10–80 mg/d; pravastatin, 10–40 mg/d; rosuvastatin, 5–40 mg/d; and simvastatin, 5–40 mg/d. These agents are usually given once a day in the evening (most cholesterol synthesis takes place overnight); at the high end of the dose ranges, twice-a-day dosing may be used. Side effects include myositis, whose incidence may be higher in patients concurrently taking fibrates or niacin. Manufacturers recommend monitoring liver and muscle enzymes. Several agents (notably erythromycin, cyclosporine, and azole antifungals) reduce the metabolism of these agents.

Fibric Acid Derivatives

The fibric acid derivatives or fibrates approved for use in the United States are gemfibrozil and fenofibrate. Ciprofibrate and bezafibrate are also available for use internationally. Gemfibrozil reduced CHD rates in hypercholesterolemic middle-aged men free of coronary disease in the Helsinki Heart Study. The effect was observed only among those who also had lower HDL cholesterol levels and high triglyceride levels. In a VA study, gemfibrozil was also shown to reduce cardiovascular events in men with existing CHD whose primary lipid abnormality was a low HDL cholesterol. There was no effect on all-cause mortality.

The fibrates are peroxisome proliferative-activated receptor-alpha (PPAR-alpha) agonists that result in potent reductions of plasma triglycerides and increases in HDL cholesterol. They reduce LDL levels by about 10–15%, although the result is quite variable, and triglyceride levels by about 40% and raise HDL levels by about 15–20%. The usual dose of gemfibrozil is 600 mg once or twice a day. Side effects include cholelithiasis, hepatitis, and myositis. The incidence of the latter two conditions may be higher among patients also taking other lipid-lowering agents. In the largest clinical trial that used clofibrate, there were significantly more deaths—especially due to cancer—in the treatment group; it should not be used.

Ezetimibe

Ezetimibe is a lipid-lowering drug that inhibits the intestinal absorption of dietary and biliary cholesterol by blocking passage across the intestinal wall by inhibiting a cholesterol transporter. The usual dose of ezetimibe is 10 mg/d orally. Ezetimibe reduces LDL cholesterol between 15% and 20% when used as monotherapy and can further reduce LDL in patients taking statins who are not yet at therapeutic goal.

However, the effects of ezetimide on CHD and its long-term safety are not yet known. Results from one small clinical trial, ENHANCE (a study of 720 persons with heterozygous familial hypercholesterolemia), showed no significant difference of intimal media thickness with ezetimibe plus an HMG-CoA reductase inhibitor compared with an HMG-CoA reductase inhibitor alone. Concern has also been raised about a greater risk of cancer with ezetimibe. A meta-analysis of three trials of ezetimibe showed no increase in cancer incidence but did find a nonsignificant increase in deaths from cancer.

Initial Selection of Medication

At present there are no absolute guidelines for selection of available lipid-modifying medications in particular patients. Nonetheless, clinical trials provide guidance

(Table 28–4). For most patients who require a lipid-modifying medication, an HMG-CoA reductase inhibitor is preferred. Although niacin will also have beneficial effects on lipids in both men and women with CHD, there is less evidence demonstrating the desired effects on CHD and all-cause mortality. Resins are the only lipid-modifying medication considered safe in pregnancy.

Table 28–4. Effects of selected lipid-modifying drugs.

Drug	**Lipid-Modifying Effects**			**Initial Daily Dose**	**Maximum Daily Dose**	**Cost for 30 Days Treatment with Dose Listed[1]**
	LDL	**HDL**	**Triglyceride**			
Atorvastatin (Lipitor)	–25 to –40%	+5 to 10%		10 mg once	80 mg once	$124.64 (20 mg once)
Cholestyramine (Questran, others)	–15 to –25%	+5%	±	4 g twice a day	24 g divided	$126.65 (8 g divided)
Colesevela	–10	+10	±	625	625 mg,	$205.20

m (WelChol)	to –20%	%		mg, 6–7 tablets once	6–7 tablets once	(6 tablets once)
Colestipol (Colestid)	–15 to –25%	+5%	±	5 g twice a day	30 g divided	$134.44 (10 g divided)
Ezetimibe (Zetia)	–20%	+5%	±	10 mg once	10 mg once	$96.35 (10 mg once)
Fenofibrate (Tricor, others)	–10 to –15%	+15 to 25%		48 mg once	145 mg once	$113.76 (20 mg once)
Fluvastatin (Lescol)	–20 to –30%	+5 to 10%		20 mg once	40 mg once	$90.40 (20 mg once)
Gemfibrozil (Lopid)	–10 to –15%	+15 to 20%		600 mg once	1200 mg divided	$74.80 (600 mg twice a day)
Lovastatin (Mevacor)	–25 to –	+5 to		10 mg	80 mg divided	$71.19 (20 mg

	40 %	10%		once		once)
Niacin (OTC, Niaspan)	–15 to –25 %	+25 to 35%		100 mg once	3–4.5 g divided	$15.28 (1.5 g twice a day, OTC) $230.83 (2 g Niaspan)
Pravastatin (Pravachol)	–25 to –40 %	+5 to 10%		20 mg once	40 mg once	$98.01 (20 mg once)
Rosuvastatin (Crestor)	–40 to –50 %	+10 to 15%		10 mg once	40 mg once	$103.24 (20 mg once)
Simvastatin (Zocor)	–25 to –40 %	+5 to 10%		5 mg once	80 mg once	$84.60 (10 mg once)

Update, Vol. 27, No. 2, February 2008. AWP may not accurately represent the actual pharmacy cost because wide contractual variations exist among institutions.

LDL, low-density lipoprotein; HDL, high-density lipoprotein; ±, variable, if any; OTC, over the counter.

Combination therapy may be used to meet lipid targets in some patients or to achieve other therapeutic goals. For example, ezetimibe plus an HMG-CoA reductase inhibitor will typically lower the LDL cholesterol more than either medication alone. Similarly, low-dose niacin (0.5–1 g/d), will substantially increase the HDL cholesterol when added to an HMG-CoA reductase inhibitor. Despite improvements in the lipid profile, however, there are few data demonstrating improved clinical outcomes of combination therapy when compared with HMG-CoA reductase inhibitors alone. Combinations may also increase the risk of complications of drug therapy. The combination of gemfibrozil and HMG-CoA reductase inhibitors increases the risk of myopathy more than either drug alone.

High Blood Triglycerides

Patients with very high levels of serum triglycerides are at risk for pancreatitis. The pathophysiology is not certain, since pancreatitis never develops in some patients with very high triglyceride levels. Most patients with congenital abnormalities in triglyceride metabolism present in childhood; hypertriglyceridemia-induced pancreatitis first presenting in adults is more commonly due to an acquired problem in lipid metabolism.

Although there are no clear triglyceride levels that predict pancreatitis, most clinicians treat fasting levels above 500 mg/dL. The risk of pancreatitis may be more related to the triglyceride level following consumption of a fatty meal. Because postprandial increases in triglyceride are inevitable if fat-containing foods are eaten, fasting triglyceride levels in persons prone to pancreatitis should be kept well below that level.

The primary therapy for high triglyceride levels is dietary, avoiding alcohol, simple sugars, refined starches, saturated and trans fatty acids, and restricting total calories. Control of secondary causes of high triglyceride levels (see Table 28–1) may also be helpful. In patients with fasting triglycerides 500 mg/dL despite adequate dietary compliance—and certainly in those with a previous episode of pancreatitis—therapy with a triglyceride-lowering drug (eg, niacin, a fibric acid derivative, or an HMG-CoA reductase inhibitor) is indicated.

Whether patients with elevated triglycerides (> 150 mg/dL) should be treated to prevent CHD is not known. Meta-analysis of 17 observational studies suggests that after adjustment for other risk factors, elevated triglycerides increased CHD risk in men by 14% and in women by 37%. Triglyceride-rich lipoproteins (partially degraded VLDL, commonly called remnant lipoproteins) have been found in human atheromas, and elevated triglycerides are associated with small dense LDL in most instances. Elevated triglycerides are also an important feature of the **metabolic syndrome**, found in an estimated 25% of Americans—defined by three or more of the following five abnormalities: waist circumference > 102 cm in men or > 88 cm in women, serum triglyceride level of at least 150 mg/dL, HDL level of < 40 mg/dL in men or < 50 mg/dL in women, blood pressure of at least 130/85 mm Hg, and serum glucose level of at least 110 mg/dL. Other data, however, suggest that triglyceride measurements do not improve discrimination between those with and without CHD events, and clinical trial data are not available to support the routine treatment of high triglycerides in all patients.

The NCEP ATP III guidelines, however, recommend an aggressive approach to triglyceride management. For those with borderline levels (150–199 mg/dL), emphasis is placed on calorie restriction and exercise. For patients with high triglycerides (> 200 mg/dL), the non-HDL cholesterol should be measured (total cholesterol – HDL cholesterol). The ATP III report recommends that non-HDL cholesterol should be treated with diet and medications to result in levels 30 mg/dL higher than the LDL goal. The ATP III report does not differentiate between primary and secondary prevention. It is reasonable to use this approach for patients with CHD and risk equivalents for that disease but not for lower-risk patients.

Nutritional Requirements

Approximately 40 nutrients are required by the human body. Nutrients are essential if they cannot be synthesized by the body and if a deficiency causes recognizable abnormalities that disappear when the deficit is corrected. Required nutrients include the essential amino acids, water-soluble vitamins, fat-soluble vitamins, minerals, and the essential fatty acids. The body also requires an adequate energy substrate, a small amount of metabolizable carbohydrate, indigestible carbohydrate (fiber), additional nitrogen, and water.

Nutritional requirements have been most commonly expressed by recommended dietary allowances (RDAs). Published and periodically reviewed by the Food and Nutrition Board of the National Academy of Sciences, the RDAs were initially designed to meet the known nutritional needs of practically all healthy persons. RDAs have been established for carbohydrate and protein; the water-soluble vitamins thiamine, riboflavin, niacin, vitamin B6, folate, vitamin B12, and vitamin C; the fat-soluble vitamins A, C, and E; and the minerals copper, phosphorus, magnesium, iron, zinc, iodine, molybdenum, and selenium.

The Food and Nutrition Board has since developed a broader approach to defining nutritional adequacy. Known as dietary reference intakes (DRIs), these guidelines go beyond the prevention of classic nutritional deficiency diseases and address the role of nutrients and other food components in long-term health and the reduction of risk of chronic diseases. The DRIs consist of four reference intakes: the RDA, the estimated average requirement (EAR), the tolerable upper intake level (UL), and the adequate intake (AI). The RDA remains the dietary intake that is sufficient to meet the nutritional requirements of nearly all individuals in an age- and gender-specific group. RDAs are intended as goals for individuals. The EAR is the intake value that is estimated to meet the requirements of 50% of individuals in an age- and gender-specific group. The UL is the maximum level of daily nutrient intake that is unlikely to pose health risks to most individuals. The AI is determined when insufficient data are available to establish the EAR and RDA for a given nutrient. It is based on fewer data and more expert opinion but is also intended as goals for individuals. The DRIs for vitamins, elements, and macronutrients are shown in eTables 29–1.1, 29–1.2 and 29–1.3.

[1] Taken from the DRI reports, see http://www.nap.edu. Recommended dietary allowances (RDAs) are in **bold type** and adequate intakes (AIs) in ordinary type followed by an asterisk (*). RDAs and AIs may both be used as goals for individual intake. RDAs are set to meet the needs of 97 ndash;98% of individuals in a group. AIs are believed to cover the needs of all individuals in a group,

though lack of or uncertainty in data prevents specification of the percentage of individuals covered by this intake.

[2] As retinol activity equivalents (RAEs): 1 RAE = 1 mcg retinol, 12 mcg -carotene, 24 mcg -carotene, or 24 mcg -cryptoxanthin. To calculate RAEs from REs of provitamin A carotenoids in foods, divide the REs by 2. For preformed vitamin A in foods or supplements and for provitamin A carotenoids in supplements, 1 RE = 1 RAE.

[3] As calciferol: 1 mcg calciferol = 40 international units of vitamin D.

[4] In the absence of adequate exposure to sunlight.

[5] As -tocopherol. -Tocopherol includes *RRR*- -tocopherol that occurs naturally in foods, and the *2R*-stereoisomeric forms of -tocopherol (*RRR*-, *RSR*-, *RRS*-, and *RSS*- -tocopherol) that occur in fortified foods and supplements. It does not include the *2S*-stereoisomeric forms of -tocopherol (*SRR*-, *SSR*-, *SRS*-, and *SSS*- -tocopherol), also found in fortified foods and supplements.

[6] As niacin equivalents (NE): 1 mg of niacin = 60 mg of tryptophan; 0–6 months = preformed niacin (not NE).

[7] As dietary folate equivalents (DFE): 1 DFE = 1 mcg food folate = 0.6 mcg of folic acid from fortified food or as a supplement consumed with food = 0.5 mcg of a supplement taken on an empty stomach.

[8] AIs have been set for choline, but there are few data to assess whether dietary choline is needed at all life stages; endogenous synthesis may suffice at some life stages.

[9] Because 10–30% of older people may malabsorb food-bound B_{12}, patients older than age 50 years should meet their RDA mainly by consuming foods fortified with B_{12} or a B_{12} supplement.

[10] Because evidence links deficient folate intake with neural tube defects in the fetus, it is recommended that all women capable of becoming pregnant consume 400 mcg of folate from supplements or fortified foods in addition to intake of food folate.

[11] Women must continue to consume 400 mcg of folate from supplements or fortified food until pregnancy is confirmed and prenatal care begins, ordinarily after the end of the periconceptional period—the critical time for formation of the neural tube.

[1] Recommended dietary allowances (RDAs) are in **bold type** and adequate intakes (AIs) in ordinary type followed by an asterisk (*). RDAs and AIs may both be used as goals for individual intake. RDAs are set to meet the needs of 97–98% of individuals in a group. AIs are believed to cover the needs of all individuals in a group, though lack of or uncertainty in data prevents specification of the percentage of individuals covered by this intake.

[2] Based on 0.8 g protein/kg body weight for reference body weight.

Reproduced, with permission, from Institute of Medicine. Committee on Use of Dietary Reference Intakes in Nutrition Labeling: Dietary reference intakes: guiding principles for nutrition labeling and fortification. National Academy of Sciences, Washington, D.C., 2003, Table C-4.

Energy

The body requires energy to support normal functions and physical activity, growth, and repair of damaged tissues. Energy is provided by oxidation of dietary protein, fat, carbohydrate, and alcohol. Oxidation of 1 g of each provides 4 kcal of energy from protein and carbohydrate, 9 kcal from fat, and 7 kcal from alcohol.

In healthy adults, energy expenditure is primarily determined by three factors: basal energy expenditure (BEE), thermic effect of food (TEF), and physical activity.

The BEE is the amount of energy required to maintain basic physiologic functions. It is measured while the subject is resting in a warm room, not having eaten for 12 hours. In healthy persons, the BEE (in kcal/24 h) can be estimated by the Harris–Benedict equation, which will correctly predict measured BEE in 90% ± 10% of healthy subjects (See Nutritional Support, below). In clinical practice, patients rarely meet the strict criteria for BEE measurement. Instead, energy expenditure is measured in individuals at rest without food for 2 hours. This measurement, the resting energy expenditure (REE), is about 10% greater than BEE.

TEF, the amount of energy expended during and following the ingestion of food, averages approximately 10% of the BEE.

Physical activity has a major impact on energy expenditure. The average energy expenditure per hour by adults engaged in typical activities is shown in eTable 29–1.4.

eTable 29–1.4. Average energy kilocalories expended per hour by adults at selected weights engaged in various activities.						
Activity	**54 kg (120 lb)**	**64 kg (140 lb)**	**73 kg (160 lb)**	**82 kg (180 lb)**	**91 kg (200 lb)**	**100 kg (220 lb)**
Sleeping: Reclining	50	58	69	78	86	99
Very light: Sitting	73	83	103	115	127	150
Light: Walking on level, shopping, light housekeeping	143	166	200	225	250	290
Moderate: Cycling, dancing, skiing, tennis	226	262	307	345	382	430
Heavy: Walking uphill, shoveling, swimming, playing basketball or football	440	512	598	670	746	840

Data from McArdle WD, et al. *Exercise Physiology: Energy, Nutrition and Human Performance*. Lea & Febiger, 1981.

Note: Range of rate of expenditure of calories per minute of activity (for a 70-kg man or a 58-kg woman): Sleeping, 0.9–1.2; very light, 1.5–2.5; light, 2–4.9; moderate, 5–7.4; and heavy, 6–12.

Protein

Protein is required for growth and for maintenance of body structure and function. Although the nutritional requirement is commonly stated in grams of protein, the true requirement is for nine **essential amino acids** plus additional nitrogen for protein synthesis. The essential amino acids are leucine, isoleucine, lysine, methionine, phenylalanine, threonine, tryptophan, valine, and histidine.

Adequate protein must be consumed each day to replace essential amino acids lost through protein turnover. On a protein-free diet, the average male loses 3.8 g of nitrogen per day—equivalent to 24 g of protein. Allowing for differences in protein quality and utilization and for individual variability, the RDA for protein is 56 g/d for men and 45 g/d for women.

Protein and energy requirements are closely related. Diets that provide insufficient energy will require additional protein to maintain nitrogen equilibrium.

Carbohydrate

A small amount of carbohydrate—approximately 100 g/d—is necessary to prevent ketosis. In practice, however, a substantial portion of dietary energy should be provided by carbohydrate. The average American diet contains 45% of calories as carbohydrate. Dietary carbohydrates include simple sugars, complex carbohydrates (starches), and indigestible carbohydrates (dietary fiber). The bulk of dietary carbohydrates should be derived from starches as found in whole grains and from sugars as found in fruits and vegetables. Sucrose and other forms of added sugar such as high fructose corn syrup are concentrated sources of calories without other sources of essential nutrients and contribute to excess calorie consumption. Sucrose consumption is also thought to be an important factor in the development of tooth decay. Starches, when unrefined, provide carbohydrate calories and vitamins, minerals, and dietary fiber.

Dietary fiber is that portion of plant foods that cannot be digested by the human intestine. Fiber increases the bulk of the stool and facilitates excretion. Diets high in dietary fiber are associated with a lower incidence of digestive and cardiovascular diseases. The more insoluble fibers, such as those found in wheat bran, have the greatest effect on colonic function. Soluble fibers such as those found in legumes, oats, and fruit result in lower blood sugar levels in diabetics and lower blood cholesterol.

Fat

Dietary fat is the most concentrated source of food energy. Like energy from dietary carbohydrate, energy derived from fat can support protein synthesis. Dietary fat also provides the essential fatty acid linoleic acid. Other than the need for adequate quantities of linoleic acid, there is no specific requirement for dietary fat as long as the diet provides adequate nutrients oxidizable for energy. Although the average American diet contains 35–40% of calories as fat, current recommendations are to limit dietary fat to 20–35% of total calories. Diets containing as little as 5–10% of total calories as fat appear to be safe and well tolerated.

Dietary fats are composed primarily of fatty acids and dietary cholesterol. Fatty acids contain either no double bonds (saturated), one double bond (monounsaturated), or more than one double bond (polyunsaturated). Saturated fatty acids are associated with increased serum cholesterol, whereas polyunsaturated and monounsaturated fatty acids lower serum cholesterol. Trans-fatty acids, a particular form of unsaturated fat found in partially hydrogenated vegetable oils, also raise serum cholesterol levels. Saturated fats are solid at room temperature and in general are derived from animal foods; unsaturated fats are liquid at room temperature and in general are derived from plant foods.

The polyunsaturated fatty acid **linoleic acid** is an essential nutrient, required by the body for the synthesis of arachidonic acid, the major precursor of prostaglandins. Deficiency of linoleic acid results in dermatitis, hair loss, and impaired wound healing. For individuals with average energy requirements, approximately 5 g of linoleic acid per day—1–2% of total calories—is required to prevent essential fatty acid deficiency.

Cholesterol is a major constituent of cell membranes. It is synthesized by the body and is not an essential nutrient. Diets that contain large amounts of cholesterol partially inhibit endogenous cholesterol synthesis but result in a net increase in serum cholesterol concentrations because of suppression of synthesis of low-density lipoprotein receptors. Average American diets contain approximately 450 mg/d of cholesterol, but 300 mg or less per day is recommended.

Vitamins

Vitamins are a heterogeneous group of organic molecules required by the body for a variety of essential metabolic functions. They are grouped as **water-soluble**

vitamins: thiamine, riboflavin, niacin, vitamin B6 (pyridoxine), vitamin B12 (cobalamin), folate, pantothenic acid, biotin, and vitamin C (ascorbic acid); and **fat-soluble vitamins:** A, D, E, and K. Disorders of vitamin metabolism are discussed below.

Minerals

The body also requires a number of inorganic minerals, commonly grouped as the **major minerals** calcium, magnesium, and phosphorus; the **electrolytes** sodium, potassium, and chloride; and the **trace elements** iron, zinc, copper, manganese, molybdenum, fluoride, iodine, cobalt, chromium, and selenium. Important characteristics of major minerals and electrolytes are summarized in eTable 29–1.5.

eTable 29–1.5. Essential macrominerals: Summary of major characteristics.

Elements	**Functions**	**Deficiency Disease or Symptoms**	**Toxicity Disease or Symptoms**[1]
Calcium	Constituent of bones, teeth; regulation of nerve,	Children: rickets. Adults: osteomalacia. May	Occurs with excess absorption due to hypervitaminosis D or

	muscle function.	contribute to osteoporosis.	hypercalcemia due to hyperparathyroidism or other causes of hypercalcemia.
Phosphorus	Constituent of bones, teeth, adenosine triphosphate, phosphorylated metabolic intermediates. Nucleic acids.	Children: rickets. Adults: osteomalacia.	Low serum Ca^{2+}:Pi ratio stimulates secondary hyperparathyroidism; may lead to bone loss.
Sodium	Principal cation in extracellular fluid. Regulates plasma volume, acid-base balance, nerve and muscle function,	Unknown on normal diet, secondary to injury or illness.	Hypertension (in susceptible individuals).

	$\mathrm{Na^+}$-$\mathrm{K^+}$-ATPase.		
Potassium	Principal cation in intracellular fluid; nerve and muscle function, $\mathrm{Na^+}$-$\mathrm{K^+}$-ATPase.	Occurs secondary to illness, injury, or diuretic therapy; muscular weakness, paralysis, mental confusion.	Cardiac arrest, small bowel ulcers.
Chloride	Fluid and electrolyte balance; gastric fluid.	Infants fed salt-free formula. Secondary to vomiting, diuretic therapy, kidney disease.	Cardiac arrest, small bowel ulcers.
Magnesium	Constituent of bones, teeth; enzyme	Secondary to malabsorption or	Depressed deep tendon reflexes and respiration.

	cofactor (kinases, etc).	diarrhea, alcoholism.	

[1] Excess mineral intake produces toxic symptoms. Unless otherwise specified, symptoms include nonspecific nausea, diarrhea, and irritability.

Modified, with permission, from Murray RK et al. *Harper's Biochemistry*, 25th ed. McGraw-Hill, 1998.

Drug-Nutrient Interactions

Many medications affect nutritional requirements. A variety of drugs induce nutrient deficiencies by appetite suppression, intestinal malabsorption, and alterations in nutrient metabolism or excretion. The effects of selected drugs on nutrient absorption and metabolism are summarized in eTable 29–1.6.

eTable 29–1.6. Effect of drugs on nutrient absorption and metabolism.

Drug	**Effect**
Analgesics and anti-inflammatories	
Salicylates	Decrease serum ascorbic acid; increase urinary loss of ascorbic acid,

	potassium, and amino acids.
Sulfasalazine	Impairs folate absorption and antagonizes folate supplementation.
Antacids	
Aluminum antacids	Decrease absorption of phosphate and vitamin A.
H_2 blockers	Decrease iron and vitamin B12 absorption.
Octreotide acetate	Hypoglycemia and hyperglycemia; decreases fat and carotene absorption.
Anticonvulsants	
Phenobarbital	Decreases serum folate; increases vitamin D and vitamin K turnover and may cause deficiency.
Phenytoin	Decreases serum folate; increases vitamin D and vitamin K turnover and may cause deficiency.
Primidone	Decreases serum folate and vitamins B_6 and B_{12}; decreases calcium absorption; increases vitamin D and vitamin K turnover and may cause anxiety.
Antimicrobials	

Neomycin	Binds bile acids. Decreases absorption of fat and carotene; of vitamins A, D, K, and B_{12}; and of potassium, sodium, calcium, and nitrogen.
Amphotericin B	Decreases serum magnesium and potassium.
Aminosalicylic acid	Increases absorption of folate, vitamin B12, iron, cholesterol, and fat.
Chloramphenicol	Increases need for vitamins B_2, B_6, B_{12}; increases serum iron.
Penicillin	Hypokalemia; renal potassium wasting.
Tetracycline	Calcium, iron, magnesium inhibit drug absorption; decreases vitamin K synthesis.
Cycloserine	May decrease absorption of calcium, magnesium; may decrease serum folate and vitamins B_6 and B_{12}; decreases protein synthesis.
Isoniazid	Vitamin B6 antagonist; may cause deficiency.

Sulfonamide	Decreases absorption of folate; decreases serum folate, iron.
Nitrofurantoin	Decreases serum folate.
Pyrimethamine	Decreases serum B_{12} and folate.
Antimitotics	
Methotrexate	Decreases activation of folate.
Colchicine	Decreases absorption of vitamin B12, carotene, fat, sodium, potassium, cholesterol, lactose, nitrogen.
Cathartics	
Phenolphthalein	Malabsorption, hypokalemia; deficiency of vitamin D, calcium.
Mineral oil	Malabsorption; decreased absorption of vitamins A, D, K.
Diuretics	Some cause hypokalemia, hypomagnesemia; may increase urinary excretion of vitamins B_1 and B_6; calcium, magnesium, potassium.
Hypocholesterolemics	
Cholestyramine	Binds bile acids; decreases absorption of fat, carotene; vitamins A, D, K, and B_{12}; folate, iron.

Clofibrate	Decreases absorption of carotene, vitamin B12, iron, glucose.
Hypotensives	
Hydralazine	Vitamin B6 deficiency.
Captopril	May cause hyponatremia, hyperkalemia; decreases taste acuity.
Oral contraceptives	Vitamin B6, folate deficiency; may increase the need for other nutrients.

Dietary Guidelines

Over the past two and a half decades, numerous authorities have published dietary guidelines that make specific nutritional recommendations. Dietary Guidelines for Americans were published by the U.S. Department of Health and Human Services and the U.S. Department of Agriculture in January 2005. These guidelines reinforce many long-standing nutritional principles while also placing greater emphasis on several recent observations. Key recommendations in the new guidelines include the following: limit the intake of saturated fat, trans fat, cholesterol, added sugars, salt, and alcohol; balance calories from food and beverages with calories expended; engage in regular physical activity at least 30–60 minutes most days of the week; consume greater quantities (up to 9 servings per day) and more varieties of fruits and vegetables per day; consume at least half of the daily grains as whole grains; consume 3 cups per day of low fat milk or milk products; consume less than 10% of calories as saturated fat, less than 300 mg/d of cholesterol, and as little trans-fatty acids as possible; consume fiber-rich fruits, vegetables, and whole grains; use little added sugars or caloric sweeteners; consume less than 2300 mg of sodium per day; use alcohol sensibly and in moderation; and prepare food safely. The guidelines also provide detailed suggestions of foods to consume to meet recommended nutrient intakes for 12 different calorie levels (eTable 29–1.7).

eTable 29–1.7. USDA food guide.

Daily Amount of Food From Each Group (vegetable subgroup amounts are per week)[1]

Discretionary calorie allowance[7]	165	171	171	132	195	267	290	362	410	426	512	648

[1] The suggested amounts of food to consume from the basic food groups, subgroups, and oils to meet recommended nutrient intakes at 12 different calorie levels. Nutrient and energy contributions from each group are calculated according to the nutrient-dense forms of

foods in each group (eg, lean meats and fat-free milk). The table also shows the discretionary calorie allowance that can be accommodated within each calorie level, in addition to the suggested amounts of nutrient-dense forms of foods in each group.

[2] Food items included in each group and subgroup:

> Fruits: All fresh, frozen, canned, and dried fruits and fruit juices: for example, oranges and orange juice, apples and apple juice, bananas, grapes, melons, berries, raisins. Only fruits and juices with no added sugars or fats are included (see note 7).
> Vegetables: Only vegetables with no added fats or sugars are included (see note 7).

- Dark green vegetables: Fresh, frozen, and canned dark green vegetables, cooked or raw: eg, broccoli; spinach; romaine; collard, turnip, and mustard greens.
- Orange vegetables: All fresh, frozen and canned orange and deep yellow vegetables, cooked or raw: eg, carrots, sweet potatoes, winter squash, and pumpkin.
- Legumes: All cooked dry beans and peas and soybean products: eg, pinto beans, kidney beans, lentils, chickpeas, tofu.
- Starchy vegetables: All fresh, frozen, and canned starchy vegetables: eg, white potatoes, corn, green

peas.

- Other vegetables: All fresh, frozen, and canned other vegetables, cooked or raw: eg, tomatoes, tomato juice, lettuce, green beans, onions.

Grains: Only grains in low-fat and low-sugar forms are included (see note 7).

- Whole grains: Whole-grain products and ingredients: eg, whole-wheat and rye breads, whole-grain cereals and crackers, oatmeal, and brown rice.
- Other grains: Refined grain products and ingredients: eg, white breads, enriched grain cereals and crackers, enriched pasta, white rice.

Meat, poultry, fish, dry beans, eggs, and nuts (meat and beans): Lean or low-fat meat, poultry, fish, dry beans and peas, eggs, nuts, seeds (see note 7). Dry beans and peas and soybean products are considered part of this group as well as the vegetable group, but should be counted in one group only.

Milk, yogurt, and cheese (milk): Fat-free or low-fat milks, yogurts, frozen yogurts, dairy desserts, cheeses (except cream cheese), including lactose-free and lactose-reduced products (see note 7). Calcium-fortified soy beverages are an option for those who want a nondairy calcium source.

[3] Quantity equivalents:

Grains: 1 ounce-equivalent (1 serving) of grains =½ cup cooked rice, pasta, or cooked cereal; 1 oz dry pasta or rice; 1 slice bread; 1 small muffin (1 oz); 1 cup ready-to-eat cereal flakes.
Fruits and vegetables: 1 cup (2 servings) of fruits or vegetables = 1 cup cut-up raw or cooked fruit or vegetable, 1 cup fruit or vegetable juice, 2 cups leafy salad greens.
Meat and beans: 1 ounce-equivalent = 1 oz lean meat, poultry, or fish; 1 egg; 1/4 cup cooked dry beans or tofu; 1 Tbsp peanut butter; ½ oz nuts or seeds.
Milk: The following each counts as 1 cup (1 serving) of milk: 1 cup milk or yogurt, 1.5 oz natural cheese such as Cheddar cheese or 2 oz processed cheese. Discretionary calories must be counted for all choices, except fat-free milk.

[4] Vegetable subgroup amounts are shown as weekly amounts, because it would be difficult for consumers to select foods from each subgroup daily. A daily amount that is one-seventh of the weekly amount listed is used in calculations of nutrient and energy levels in each pattern.

[5] The whole grain subgroup amounts shown represent at least three 1-oz servings and one-half of the total amount as whole grains for all calorie levels of 1600 and above. This is the minimum suggested amount of whole grains to consume as part of the food patterns. More whole grains

up to all the grains recommended may be selected, with offsetting decreases in the amounts of other (enriched) grains. In patterns designed for younger children (1000, 1200, and 1400 calories), one-half of the total amount of grains is shown as whole grains.

[6] Oils shown represent the amounts that are added to foods during processing, cooking, or at the table. Oils and soft margarines include vegetable oils and soft vegetable oil table spreads that have no trans fats. The oils listed are a major source of dietary vitamin E and polyunsaturated fatty acids, including the essential fatty acids. In contrast, solid fats are listed separately in the discretionary calorie category. The amounts of each type of fat in the food intake pattern were based on 60% oils and/or soft margarines with no trans fats and 40% solid fat. The typical American diet contains about 42% oils or soft margarines and about 58% solid fats.

[7] The discretionary calorie allowance is the remaining amount of calories in each food pattern after selecting the specified number of nutrient-dense forms of foods in each food group. The number of discretionary calories assumes that food items in each food group are selected in nutrient-dense forms (that is, forms that are fat free or low fat and that contain no added sugars). Solid fat and sugar calories always need to be counted as discretionary calories:

The fat in low-fat, reduced fat, or whole milk or milk products or cheese and the sugar and fat in chocolate milk, ice cream, pudding, etc.

The fat in higher fat meats (eg, ground beef with more than 5% fat by weight, poultry with skin, higher fat luncheon meats, sausages).

The sugars added to fruits and fruit juices with added sugars or fruits canned in syrup.

The added fat and/or sugars in vegetables prepared with added fat or sugars.

The added fats and/or sugars in grain products containing higher levels of fats and/or sugars (eg, sweetened cereals, higher fat crackers, pies and other pastries, cakes, cookies).

Total discretionary calories should be limited to the amounts shown in the table at each calorie level. The nutrient goals for the 1600-calorie pattern are set to meet the needs of adult women, which are higher and require that more calories be used in selections from the basic food groups.

Assessment of Nutritional Status

No single biochemical test or clinical technique is sufficiently accurate to serve as a reliable test for malnutrition. Techniques of nutritional assessment utilize a combination of methods, including evaluation of dietary intake, anthropometric measurements, clinical examination, and laboratory tests.

Dietary History

Patients undergoing a history and physical examination should be asked questions to help identify those high-risk patients who require further evaluation for malnutrition. Of particular importance are the regularity and availability of meals; who does the shopping and food preparation; recent changes in appetite, intake, or body weight; use of special diets or dietary supplements; use of alcohol, drugs, or medications; food preferences and food allergies; and the presence of illnesses affecting nutritional intakes, losses, or requirements. Elderly and adolescent patients, pregnant or lactating women, and the poor and socially isolated are at particular risk for nutritional problems.

Further quantification of dietary intake can be performed using a variety of techniques. **Twenty-four-hour diet recalls** provide rough estimates of nutrient intakes. Patients are asked to describe their dietary intake over the preceding day, including snacks, beverages, and alcohol. Problems with this technique include poor patient recall, difficulties in estimating serving sizes, and the inaccuracy associated with generalizing from a single day's intake. More accurate information can be obtained by asking patients to complete a **3- to 5-day diet record**. Nutrient composition can then be analyzed with the aid of standard handbooks or computer software. Although prospective and less likely to be invalidated by memory lapses, omissions are still common, and the usual difficulties in estimating serving sizes persist.

Clinical Examination

A nutritionally focused physical examination should be performed on each patient at risk for nutritional problems. The examination targets body weight, muscle wasting, fat stores, volume status, and signs of micronutrient deficiencies (eTable 29–1.8).

eTable 29–1.8. Clinical signs that may be due to nutrient deficiency.

Clinical Sign	**Nutrient Deficiency**	**Clinical Sign**	**Nutrient Deficiency**
Hair		**Neck**	
Transverse depigmentation	Protein, copper	Goiter	Iodine
Easily pluckable	Protein	**Chest**	
Sparse and thin	Protein, zinc, biotin	Thoracic rosary	Vitamin D
Skin		**Heart**	

Dry, scaling	Zinc, vitamin A, essential fatty acids	High-output failure	Thiamine
		Decreased output	Protein–calorie
Flaky paint dermatitis	Protein, niacin, riboflavin	**Abdomen**	
Follicular hyperkeratosis	Vitamins A and C	Hepatosplenomegaly	Protein–calorie
Perifollicular petechiae	Vitamin C	Distention	Protein–calorie
Petechiae, purpura	Vitamins C and K	Diarrhea	Niacin, folate, vitamin B12
Pigmentation, desquamation	Niacin	**Extremities**	
		Muscle tenderness, pain	Thiamine, vitamin C
Nasolabial seborrhea	Niacin, riboflavin, pyridoxine	Muscle wasting	Protein–calorie
Pallor	Iron, folate,	Edema	Protein, thiamine

	vitamin B12, copper		
Scrotal/vulvar dermatoses	Riboflavin	Bone tenderness	Vitamin C, vitamin D, calcium, phosphorus
Subcutaneous fat loss	Calories		
Nails		**Neurologic**	
Spooning	Iron	Hyporeflexia	Thiamine
Transverse lines, ridging	Protein–calorie	Decreased position and vibratory sense	Vitamin B12, thiamine
Head			
Temporal muscle wasting	Protein–calorie	Paresthesias	Vitamin B12, thiamine, niacin
Parotid enlargement	Protein	Confabulation, disorientation	Thiamine
Eyes			
Night blindness	Vitamin A, zinc	Dementia	Niacin

Corneal vascularization	Riboflavin	Ophthalmoplegia	Thiamine, phosphorus
Xerosis, Bitot spots, keratomalacia	Vitamin A	Tetany	Calcium, magnesium
		Other	
Conjunctival inflammation	Riboflavin	Delayed wound healing	Zinc, protein–calorie, vitamin C
Mouth			
Glossitis (scarlet, raw)	Niacin, pyridoxine, riboflavin, vitamin B12, folate		
Bleeding gums	Vitamin C, riboflavin		
Cheilosis, angular stomatitis	Riboflavin		
Atrophic lingual	Niacin, iron,		

papillae	riboflavin, folate, vitamin B12		
Hypogeusia	Zinc, vitamin A		
Tongue fissuring	Niacin		

Evaluation of body weight is particularly useful. Body weight in relation to height can be assessed as the **body mass index (BMI)**—weight (in kilograms)/height (in meters)^2 (eTable 29–1.9). In adult patients, however, a recent unintentional change in body weight is usually a better index of undernutrition than a low BMI. This change is best expressed as a percentage of usual weight lost per unit of time. A weight loss of 10% or more of usual weight within a period of 1–2 months is generally considered to be predictive of a poor clinical outcome.

eTable 29–1.9. Body mass index chart.[1]																	
Body Mass Index

[1] To use this table, find the appropriate height in the left-hand column. Move across to a given weight. The number at the top of the column is the BMI at that height and weight. Pounds have been rounded off. A normal BMI is 18.5–24.9. Overweight is defined as a BMI of 25–29.9. Class I obesity is 30–34.9; class II obesity is a BMI of 35–39.9; and class III (extreme) obesity is a BMI of > 40.

Evaluation of body composition—particularly fat stores and skeletal muscle—can be performed by visual inspection or, more quantitatively, by using **anthropometric measurements**. The most commonly used are the triceps skin fold and mid arm muscle circumference. Because of variations in measurement, they have limited clinical utility.

A number of more sophisticated techniques are available for assessment of body composition. Most have little role in patient care. These include bioelectrical impedance, dual-energy x-ray absorptiometry, air-displacement plethysmography, hydrodensitometry, spectroscopy and mass spectrometry, neutron activation analysis, and MRI and body line scanners.

Laboratory Tests

Serum albumin is the most important laboratory test for the diagnosis of protein–calorie undernutrition. Most patients with severe protein depletion will have low serum albumin levels. Many nonnutritional conditions can also reduce serum albumin—particularly liver disease and severe illness in general. Other serum proteins with shorter half-lives (such as transferrin, transthyretin, and prealbumin) may reflect short-term changes in nutritional status but suffer from similar shortcomings.

Tests of cellular immunity are also abnormal in many patients with protein–calorie undernutrition. Measurements of the **total lymphocyte count** and **delayed hypersensitivity reactions** to common skin test antigens are nonspecific; abnormalities may be due to nonnutritional factors.

Despite their poor specificity, these tests are useful prognostically. Patients with abnormal nutritional assessment parameters have a markedly increased risk of

poor clinical outcomes.

Protein–Energy Malnutrition

Essentials of Diagnosis

- History of decreased intake of energy or protein, increased nutrient losses, or increased nutrient requirements.
- Manifestations range from weight loss and growth failure to distinct syndromes, kwashiorkor, and marasmus.
- In severe cases, virtually all organ systems are

affected.
- Protein loss correlates with weight loss: 35–40% total body weight loss is usually fatal.

General Considerations

Protein–energy malnutrition occurs as a result of a relative or absolute deficiency of energy and protein. It may be primary, due to inadequate food intake, or secondary, as a result of other illness. For most developing nations, primary protein–energy malnutrition remains among the most significant health problems. Protein–energy malnutrition has been described as two distinct syndromes. **Kwashiorkor**, caused by a deficiency of protein in the presence of adequate energy, is typically seen in weaning infants at the birth of a sibling in areas where foods containing protein are insufficiently abundant. **Marasmus**, caused by combined protein and energy deficiency, is most commonly seen where adequate quantities of food are not available.

In industrialized societies, protein–energy malnutrition is most often secondary to other diseases. **Kwashiorkor-like secondary protein–energy malnutrition** occurs primarily in association with hypermetabolic acute illnesses such as trauma, burns, and sepsis. **Marasmus-like secondary protein–energy malnutrition** typically results from chronic diseases such as chronic obstructive pulmonary disease (COPD), congestive heart failure, cancer, or AIDS. These syndromes have been estimated to be present in at least 20% of hospitalized patients. A substantially greater number of patients have risk factors that could result in these syndromes. In both syndromes, protein–energy malnutrition is caused either by decreased intake of energy and protein, increased nutrient losses, or increased nutrient requirements dictated by the underlying illness. For example, diminished oral intake may result from poor dentition or various gastrointestinal disorders. Loss of nutrients results from malabsorption and diarrhea as well as from glycosuria. Nutrient requirements are increased by fever, surgery, neoplasia, and burns.

Pathophysiology

Protein–energy malnutrition affects every organ system. The most obvious results are loss of body weight, adipose stores, and skeletal muscle mass. Weight losses of 5–10% are usually tolerated without loss of physiologic function; losses of 35–40% of body weight usually result in death. Loss of protein from skeletal muscle and internal organs is usually proportionate to weight loss. Protein mass is lost from the liver, gastrointestinal tract, kidneys, and heart.

As protein–energy malnutrition progresses, organ dysfunction develops. Hepatic synthesis of serum proteins decreases, and depressed levels of circulating proteins are observed. Cardiac output and contractility are decreased, and the electrocardiogram (ECG) may show decreased voltage and a rightward axis shift. Autopsies of patients who die with severe undernutrition show myofibrillar atrophy and interstitial edema of the heart.

Respiratory function is affected primarily by weakness and atrophy of the muscles of respiration. Vital capacity and tidal volume are depressed, and mucociliary clearance is abnormal. The gastrointestinal tract is affected by mucosal atrophy and loss of villi of small intestine, resulting in malabsorption. Intestinal disaccharidase deficiency and mild pancreatic insufficiency also occur.

Changes in immunologic function are among the most important changes seen in protein–calorie undernutrition. T lymphocyte number and function are depressed. Changes in B cell function are more variable. Impaired complement activity, granulocyte function, and anatomic barriers to infection are noted, and wound healing is poor.

Clinical Findings

The clinical manifestations of protein–energy malnutrition range from mild growth retardation and weight loss to a number of distinct clinical syndromes (eTable 29–1.8). Children in the developing world manifest marasmus and kwashiorkor. In secondary protein–energy malnutrition as seen in industrialized nations, clinical manifestations are affected by the degree of protein and energy deficiency, the underlying illness that resulted in the deficiency, and the patient's nutritional status prior to illness.

Progressive wasting that begins with weight loss and proceeds to more severe cachexia typically develops in most patients with marasmus-like secondary protein–energy malnutrition. In the most severe form of this disorder, most body fat stores disappear and muscle mass decreases, most noticeably in the temporalis and interosseus muscles. Laboratory studies may be unremarkable—serum albumin, for example, may be normal or slightly decreased, rarely decreasing to < 2.8 g/dL. In contrast, owing to its rapidity of onset, kwashiorkor-like secondary protein–energy malnutrition may develop in patients with normal subcutaneous fat and muscle mass or, if the patient is obese, in patients with excess fat and muscle. The serum protein level, however, typically declines and the serum albumin is often < 2.8 g/dL. Dependent edema, ascites, or anasarca may develop. As with primary protein–energy malnutrition, combinations of the marasmus-like and kwashiorkor-like syndromes can occur simultaneously, typically in patients with progressive chronic disease in whom a superimposed acute illness develops.

Treatment

The treatment of severe protein–energy malnutrition is a slow process requiring great care. Initial efforts should be directed at correcting fluid and electrolyte abnormalities and infections. Of particular concern are depletion of potassium, magnesium, and calcium and acid–base abnormalities. The second phase of treatment is directed at repletion of protein, energy, and micronutrients. Treatment is started with modest quantities of protein and calories calculated according to the patient's actual body weight. Adult patients are given 1 g of protein and 30 kcal/kg. Concomitant administration of vitamins and minerals is obligatory. Either the enteral or parenteral route can be used, although the former is preferable. Enteral fat and lactose are withheld initially. Patients with less severe protein–calorie undernutrition can be given calories and protein simultaneously with the correction of fluid and electrolyte abnormalities. Similar quantities of protein and calories are recommended for initial treatment.

Patients treated for protein–energy malnutrition require close follow-up. In adults, both calories and protein are advanced as tolerated, adults to 1.5 g/kg/d of protein and 40 kcal/kg/d of calories.

Patients who are re-fed too rapidly may develop a number of untoward clinical sequelae. During refeeding, circulating potassium, magnesium, phosphorus, and glucose move intracellularly and can result in low serum levels of each. The administration of water and sodium with carbohydrate refeeding can overload hearts with depressed cardiac function and result in congestive heart failure. Enteral refeeding can lead to malabsorption and diarrhea due to abnormalities in the gastrointestinal tract.

Refeeding edema is a benign condition to be differentiated from congestive heart failure. Changes in renal sodium reabsorption and poor skin and blood vessel integrity result in the development of dependent edema without other signs of heart disease. Treatment includes reassurance, elevation of the dependent area, and modest sodium restriction. Diuretics are usually ineffective, may aggravate electrolyte deficiencies, and should not be used.

The prevention and early detection of protein–energy malnutrition in hospitalized patients require awareness of its risk factors and early symptoms and signs. Patients at risk require formal assessment of nutritional status and close observation of dietary intake, body weight, and nutritional requirements during the hospital stay.

Obesity

Essentials of Diagnosis

- Excess adipose tissue, resulting in BMI > 30.
- Upper body obesity (abdomen and flank) of greater health consequence than lower body obesity (buttocks and thighs).
- Associated with multiple metabolic and structural disorders, including diabetes mellitus, hypertension, and hyperlipidemia.

General Considerations

Obesity is one of the most common disorders in medical practice and among the most frustrating and difficult to manage. Little progress has been made in prevention or treatment, yet major changes have occurred in our understanding of its causes and its implications for health.

Definition & Measurement

See Related Guideline from *CURRENT Practice Guidelines in Primary Care 2009*

Obesity is defined as an excess of adipose tissue. Accurate quantification of body fat requires sophisticated techniques not usually available in clinical practice. Physical examination is usually sufficient to detect excess body fat. More quantitative evaluation is performed by calculating the BMI.

The **BMI** closely correlates with excess adipose tissue. It is calculated by dividing measured body weight in kilograms by the height in meters squared (eTable 29–1.9).

The National Institutes of Health (NIH) define a normal BMI as 18.5–24.9. Overweight is defined as BMI = 25–29.9. Class I obesity is 30–34.9, class II obesity is 35–39.9, and class III (extreme) obesity is BMI > 40. Factors other than total weight, however, are also important. Upper body obesity (excess fat around the waist and flank) is a greater health hazard than lower body obesity (fat in the thighs and buttocks). Obese patients with increased abdominal circumference (> 102 cm in men and 88 cm in women) or with high waist–hip ratios (> 1.0 in men and > 0.85 in women) have a greater risk of diabetes mellitus, stroke, coronary artery disease, and early death than equally obese patients with lower ratios. Further differentiation of the location of excess fat suggests that visceral fat within the abdominal cavity is more hazardous to health than subcutaneous fat around the abdomen.

See Related Guideline from *CURRENT Practice Guidelines in Primary Care 2009*

Current U.S. survey data demonstrate that 65% of Americans are overweight and 30.4% are obese. Women in the United States are more apt to be obese than men, and African American and Mexican-American women are more obese than whites. The poor are more obese than the rich regardless of race.

Health Consequences of Obesity

Obesity is associated with significant increases in both morbidity and mortality. A great many disorders occur with greater frequency in obese people (see illustration). The most important and common of these are hypertension, type 2 diabetes mellitus, hyperlipidemia, coronary artery disease, degenerative joint disease, and psychosocial disability. Approximately 60% of individuals with obesity in the United States have the metabolic syndrome (including three or more of the following factors: elevated abdominal circumference, blood pressure, blood triglycerides, and fasting blood sugar, and low high-density lipoprotein [HDL] cholesterol). Certain cancers (colon, ovary, and breast), thromboembolic disorders, digestive tract diseases (gallbladder disease, gastroesophageal reflux disease), and skin disorders are also more prevalent in the obese. Surgical and obstetric risks are greater. Obese patients also have a greater risk of pulmonary functional impairment including sleep apnea, endocrine abnormalities, proteinuria, and increased hemoglobin concentration. Patients with obesity have increased rates of major depression and binge eating disorder. Several studies have documented that obese individuals are also subject to various forms of social discrimination.

Fig.

Role of obesity in the pathophysiology of disease. Some ways whereby obesity contributes to disease. Short arrows refer to a change in the indicated parameter, and long arrows indicate a consequence of that change. In some cases, evidence is epidemiologic; in others, it is experimental. (Modified and reproduced, with permission, from Bray GA: Pathophysiology of obesity. Am J Clin Nutr 1992;55:488S.)

In young and middle-aged adults, mortality from all causes and mortality from cardiovascular disease increase in proportion to the degree of obesity. The relative risk associated with obesity, however, decreases with age, and weight is no longer a risk factor in adults over age 75 years. Recent analysis of data from the National Health and Nutrition Examination Survey (NHANES) has suggested that lesser amounts of excess weight (BMI between 25 and 29.9) may not be associated with excess mortality.

Etiology

Until recently, obesity was considered to be the direct result of a sedentary lifestyle plus chronic ingestion of excess calories. Although these factors are undoubtedly the principal cause in many cases, there is evidence for strong genetic influences on the development of obesity. Adopted children demonstrate a close relationship between their body mass index and that of their biologic parents. No such relationship is found between the children and their adoptive parents. Twin studies also demonstrate substantial genetic influences on BMI with little influence from the childhood environment. As much as 40–70% of obesity may be explained by genetic influences.

Genetic determinants of some types of obesity have now been established. Five genes affecting control of appetite have been identified in mice. Mutations of each gene result in obesity, and each has a human homolog. One gene codes for a protein expressed by adipose tissue—leptin—and another for the leptin receptor in the brain. The other three genes affect brain pathways downstream from the leptin receptor. Numerous other candidate genes for human obesity have been identified. Only a small percentage (4–6%) of human obesity is thought to be due to single gene mutations. Most human obesity undoubtedly develops from the interactions of multiple genes, environmental factors, and behavior. The rapid increase in obesity in the last several decades clearly points to a major role of environmental factors in the development of obesity.

Medical Evaluation of the Obese Patient

Historical information should be obtained about age at onset, recent weight changes, family history of obesity, occupational history, eating and exercise behavior, cigarette and alcohol use, previous weight loss experience, and psychosocial factors including assessment for depression and eating disorders. Particular attention should be directed at use of laxatives, diuretics, hormones, nutritional supplements, and over-the-counter medications.

Physical examination should assess the degree and distribution of body fat, overall nutritional status, and signs of secondary causes of obesity.

Less than 1% of obese patients have an identifiable secondary, nonpsychiatric, cause of obesity. Hypothyroidism and Cushing syndrome are important examples that can usually be diagnosed by physical examination in patients with unexplained recent weight gain. Such patients require further endocrinologic evaluation, including serum thyroid-stimulating hormone (TSH) determination and dexamethasone suppression testing (see Chapter 26: Endocrine Disorders).

All obese patients should be assessed for medical consequences of their obesity by screening for the metabolic syndrome. Blood pressure, waist circumference, fasting glucose, low-density lipoprotein [LDL] and HDL cholesterol, and triglycerides should be measured.

Treatment

See Related Guideline from *CURRENT Practice Guidelines in Primary Care 2009*

Using conventional dietary techniques, only 20% of patients will lose 20 lb and maintain the loss for over 2 years; 5% will maintain a 40-lb loss. Average weight loss is approximately 7% of baseline weight. Continued close provider–patient contact appears to be more important for success of treatment than the specific features of any given treatment regimen. Careful patient selection will improve success rates and decrease frustration of both patients and therapists. Only sufficiently motivated patients should enter active treatment programs. Specific attempts to identify motivated patients—eg, requesting a 3-day diet record—are often useful.

Most successful programs employ a multidisciplinary approach to weight loss, with hypocaloric diets, behavior modification to change eating behavior, aerobic exercise, and social support. Emphasis must be on *maintenance* of weight loss.

Dietary instructions for most patients incorporate the same principles that apply to healthy people who are not obese. This is achieved by emphasizing intake of a wide variety of predominantly "unprocessed" foods. Special attention is usually paid to limiting foods that provide large amounts of calories without other nutrients, ie, fat, sucrose, and alcohol. There is no physiologic advantage to diets that restrict carbohydrates, advocate relatively larger amounts of protein or fats, or recommend ingestion of foods one at a time. Diets that are restricted in carbohydrates, however, can be effective in achieving a lower total calorie intake. Several studies have demonstrated that low-carbohydrate diets can be used safely for weight loss without adverse effects on lipids or other metabolic parameters. Meal replacement diets can also be used effectively and safely to achieve weight loss.

Long-term changes in eating behavior are required to maintain weight loss. Although formal **behavior modification** programs are available to which patients can be referred, the clinician caring for obese patients can teach a number of useful behavioral techniques. The most important technique is to emphasize planning and record keeping. Patients can be taught to plan menus and exercise sessions and to record their actual behavior. Record keeping not only aids in behavioral change, but also helps the provider to make specific suggestions for problem solving. Patients can be taught to recognize "eating cues" (emotional, situational, etc) and how to avoid or control them. Regular self-monitoring of weight is also associated with improved long-term weight maintenance.

Exercise offers a number of advantages to patients trying to lose weight and keep it off. Aerobic exercise directly increases the daily energy expenditure and is particularly useful for long-term weight maintenance. Exercise will also preserve lean body mass and partially prevent the decrease in basal energy expenditure (BEE) seen with semistarvation. When compared with no treatment, exercise alone results in small amounts of weight loss. Exercise plus diet results in greater weight loss than diet alone. A greater intensity of exercise is associated with a greater amount of weight loss. Up to 1 hour of moderate exercise per day is associated with long-term weight maintenance in individuals who have successfully lost weight. **Social support** is essential for a successful weight loss program. Continued close contact with clinicians and involvement of the family and peer group are useful techniques for reinforcing behavioral change and preventing social isolation.

Patients with severe obesity may require more aggressive treatment regimens. **Very-low-calorie diets** (800 kcal/d) result in rapid weight loss and marked initial improvement in obesity-related metabolic complications. Patients are commonly maintained on such programs for 4–6 months and lose an average of 2 lb per week. Average weight loss is approximately 15% of initial weight. Most programs use meal replacement diets to achieve the very-low-calorie intake. Long-term weight maintenance is less predictable and requires concurrent behavior modification, long-term use of low-calorie diets, careful self-monitoring, and regular exercise. Side effects such as fatigue, orthostatic hypotension, cold intolerance, and fluid and electrolyte disorders are observed in proportion to the degree of calorie reduction and require regular supervision by a physician. Other less common complications include gout, gallbladder disease, and cardiac arrhythmias. Although weight loss is more rapidly achieved with very-low-calorie diets as compared with traditional diets, long-term outcomes are equivalent.

Medications for the treatment of obesity are available both over the counter and by prescription. Considerable controversy exists as to the appropriate use of medications for obesity. NIH clinical obesity guidelines state that obesity drugs may be used as part of a comprehensive weight loss program for patients with BMI > 30 or those with BMI > 27 with obesity-related risk factors. There are few data, however, to suggest that medications can improve long-term outcomes associated with obesity.

Several medications are approved by the US Food and Drug Administration (FDA) for treatment of obesity. Catecholaminergic medications (eg, phentermine, diethylpropion, mazindol) are approved for short-term use only and have limited utility. Two additional medications are approved for weight loss: sibutramine and orlistat.

Sibutramine blocks uptake of both serotonin and norepinephrine in the central nervous system. Orlistat reduces fat absorption in the gastrointestinal tract.

Sibutramine , typically at doses of 10 mg/d, results in average weight losses of 3–5 kg more than placebo in studies extending over 6–12 months. Sibutramine also appears to improve 1-year outcomes in patients on very-low-calorie diets. Side effects include dry mouth, anorexia, constipation, insomnia, and dizziness. In some patients (< 5%), sibutramine may substantially increase blood pressure.

Orlistat is the first approved medication for obesity that works in the gastrointestinal tract rather than the central nervous system. By inhibiting intestinal lipase, orlistat reduces fat absorption. As expected, orlistat may result in diarrhea, gas, and cramping and perhaps also reduced absorption of fat-soluble vitamins. In randomized trials with up to 2 years of follow-up, orlistat has resulted in 2–4 kg greater weight loss than placebo. The recommended dose of orlistat is 120 mg three times daily with meals. A 60-mg dose is available over-the-counter in the United States. Despite FDA approval of sibutramine and orlistat and NIH guidelines supporting their use, long-term clinical benefits have not been demonstrated. Although these medications result in some additional weight loss at the end of 1- and 2-year clinical trials and, in some studies, improved obesity-related metabolic parameters, a beneficial impact of these medications on obesity-related clinical outcomes has not been established. Another class of medications under investigation is selective cannabinoid-1 receptor antagonists (eg, rimonabant). In four initial year-long studies of rimonabant, a 20-mg dose resulted in 5 kg greater weight loss than placebo. Rimonabant, however, caused more adverse affects than placebo, including nervous system, psychiatric, and gastrointestinal symptoms, and attrition rates at 1 year were approximately 40%. Because of concerns related to depression and suicidality, the FDA did not approve rimonabant for use in the United States.

Bariatric surgery is an increasingly prevalent treatment option for patients with severe obesity. In the United States, gastric operations are considered the procedures of choice. Most popular is the Roux-en-Y gastric bypass (RYGB). In most centers, the operation can be done laparoscopically. RYGB typically results in substantial amounts of weight loss—close to 50% of initial body weight in some studies. Complications occur in up to 40% of persons undergoing RYGB surgery and include peritonitis due to anastomotic leak, abdominal wall hernias, staple line disruption, gallstones, neuropathy, marginal ulcers, stomal stenosis, wound infections, thromboembolic disease, gastrointestinal symptoms, and nutritional deficiencies including iron, vitamin B_{12}, folate, calcium, and vitamin D. Operative mortality rates within 30 days are nil to 1% in low-risk populations but have been reported to be substantially higher in Medicare beneficiaries. One-year mortality rates have been reported as high as 7.5% in men with Medicare. The surgical volume (the number of cases performed by the surgeon or hospital) has been demonstrated to be an important predictor of outcome. Gastric banding (GB) surgeries are increasing as an alternative procedure. GB results in less dramatic weight loss than RYGB but with fewer short-term complications. Frequent follow-up is required to adjust the gastric band. Longer-term follow-up suggests that both procedures are associated with significant regaining of weight. NIH consensus panel recommendations are to limit obesity surgery to patients with BMIs over 40, or over 35 if obesity-related comorbidities are present. The procedure is cost-effective for patients with severe obesity and most third-party payers now cover the procedure in selected patients. Recent outcomes studies have suggested that bariatric surgery is associated with a significant reduction in deaths at 11-year follow-up. In one prospective study, the number needed to treat to prevent one death in 11 years was 77 operations.

When to Refer

Patients with BMI over 40 (or over 35 with obesity-related morbidities) who are interested in considering weight loss surgery.

Anorexia Nervosa

Essentials of Diagnosis

- Disturbance of body image and intense fear of becoming fat.
- Weight loss leading to body weight 15% below expected.
- In females, absence of three consecutive menstrual cycles.

General Considerations

Anorexia nervosa typically begins in the years between adolescence and young adulthood. Ninety percent of patients are females, most from the middle and upper socioeconomic strata. The diagnosis is based on weight loss leading to body weight 15% below expected, a distorted body image, fear of weight gain or of loss of control over food intake and, in females, the absence of at least three consecutive menstrual cycles. Other medical or psychiatric illnesses that can account for anorexia and weight loss must be excluded.

The prevalence of anorexia nervosa is greater than previously suggested. In Rochester, Minnesota, for example, the prevalence per 100,000 population is estimated to be 270 for females and 22 for males. Many other adolescent girls have features of the disorder without the severe weight loss.

The cause of anorexia nervosa is not known. Although multiple endocrinologic abnormalities exist in these patients, most authorities believe they are secondary to malnutrition and not primary disorders. Most experts favor a primary psychiatric origin, but no hypothesis explains all cases. The patient characteristically comes from a family whose members are highly goal and achievement oriented. Interpersonal relationships may be inadequate or destructive. The parents are usually overly directive and concerned with slimness and physical fitness, and much of the family conversation centers around dietary matters. One theory holds that the patient's refusal to eat is an attempt to regain control of her body in defiance of parental control. The patient's unwillingness to inhabit an "adult body" may also represent a rejection of adult responsibilities and the implications of adult interpersonal relationships. Patients are commonly perfectionistic in behavior and exhibit obsessional personality characteristics. Marked depression or anxiety may be present.

Clinical Findings

Symptoms and Signs

Patients with anorexia nervosa may exhibit severe emaciation and may complain of cold intolerance or constipation. Amenorrhea is almost always present. Bradycardia, hypotension, and hypothermia may be present in severe cases. Examination demonstrates loss of body fat, dry and scaly skin, and increased lanugo body hair. Parotid enlargement and edema may also occur.

Laboratory Findings

Laboratory findings are variable but may include anemia, leukopenia, electrolyte abnormalities, and elevations of blood urea nitrogen (BUN) and serum creatinine. Serum cholesterol levels are often increased. Endocrine abnormalities include depressed levels of luteinizing and follicle-stimulating hormones and impaired response of luteinizing hormone to luteinizing hormone-releasing hormone.

Diagnosis & Differential Diagnosis

The diagnosis can be difficult, since many common social and cultural factors promote and maintain anorexic behavior. The diagnosis depends on identification of the common behavioral features and exclusion of medical disorders that would account for weight loss.

Behavioral features required for the diagnosis include intense fear of becoming obese, disturbance of body image, weight loss of at least 15%, and refusal to exceed a minimal normal weight.

The differential diagnosis includes endocrine and metabolic disorders, such as panhypopituitarism, Addison disease, hyperthyroidism, and diabetes mellitus;

gastrointestinal disorders, such as Crohn disease and celiac sprue; chronic infections and cancers, such as tuberculosis and lymphoma; and rare central nervous system disorders such as hypothalamic tumors.

Treatment

The goal of treatment is restoration of normal body weight and resolution of psychological difficulties. Hospitalization may be necessary. Treatment programs conducted by experienced teams are successful in about two-thirds of cases, restoring normal weight and menstruation. One-half continue to experience difficulties with eating behavior and psychiatric problems. Occasional patients with anorexia develop obesity after treatment. Two to 6% of patients die of the complications of the disorder or commit suicide.

Various treatment methods have been used without clear evidence of superiority of one over another. Supportive care by physicians and nurses is probably the most important feature of therapy. Structured behavioral therapy, intensive psychotherapy, and family therapy may be tried. A variety of medications including tricyclic antidepressants, SSRIs, and lithium carbonate are effective in some cases; overall, however, clinical trial results have been disappointing. Patients with severe malnutrition must be hemodynamically stabilized and may require enteral or parenteral feeding. Forced feedings should be reserved for life-threatening situations, since the goal of treatment is to reestablish normal eating behavior.

When to Refer

- Adolescents and young adults with otherwise unexplained weight loss should be evaluated by a psychiatrist.
- All patients with diagnosed anorexia nervosa should be co-managed with a psychiatrist.

When to Admit

- Signs of hypovolemia, major electrolyte disorders, and severe protein-energy malnutrition.
- Failure to improve with outpatient management.

Bulimia Nervosa

Essentials of Diagnosis

- Uncontrolled episodes of binge eating at least twice weekly for 3 months.
- Recurrent inappropriate compensation to prevent weight gain such as self-induced vomiting, laxatives,

diuretics, fasting, or excessive exercise.
- Overconcern with weight and body shape.

General Considerations

Bulimia nervosa is the episodic uncontrolled ingestion of large quantities of food followed by recurrent inappropriate compensatory behavior to prevent weight gain such as self-induced vomiting, diuretic or cathartic use, or strict dieting or vigorous exercise.

Like anorexia nervosa, bulimia nervosa is predominantly a disorder of young, white, middle- and upper-class women. It is more difficult to detect than anorexia, and some studies have estimated that the prevalence may be as high as 19% in college-aged women.

Clinical Findings

Patients with bulimia nervosa typically consume large quantities of easily ingested high-calorie foods, usually in secrecy. Some patients may have several such episodes a day for a few days; others report regular and persistent patterns of binge eating. Binging is usually followed by vomiting, cathartics, or diuretics and is usually accompanied by feelings of guilt or depression. Periods of binging may be followed by intervals of self-imposed starvation. Body weights may fluctuate but generally are within 20% of desirable weights.

Some patients with bulimia nervosa also have a cryptic form of anorexia nervosa with significant weight loss and amenorrhea. Family and psychological issues are generally similar to those encountered among patients with anorexia nervosa. Bulimics, however, have a higher incidence of premorbid obesity, greater use of cathartics and diuretics, and more impulsive or antisocial behavior. Menstruation is usually preserved.

Medical complications are numerous. Gastric dilatation and pancreatitis have been reported after binges. Vomiting can result in poor dentition, pharyngitis, esophagitis, aspiration, and electrolyte abnormalities. Cathartic and diuretic abuse also cause electrolyte abnormalities or dehydration. Constipation and hemorrhoids are common.

Treatment

Treatment of bulimia nervosa and bulimarexia requires supportive care and psychotherapy. Individual, group, family, and behavioral therapy have all been utilized. Antidepressant medications may be helpful. The best results have been with fluoxetine hydrochloride and other SSRIs. Although death from bulimia is rare, the long-term psychiatric prognosis in severe bulimia is worse than that in anorexia nervosa..

When to Refer

All patients with diagnosed bulimia should be co-managed with a psychiatrist.

Disorders of Vitamin Metabolism

Deficiencies of single vitamins are less often encountered than those of multiple vitamins. Although any cause of protein–calorie undernutrition can result in concurrent vitamin deficiency, most deficiencies are associated with malabsorption, alcoholism, medications, hemodialysis, total parenteral nutrition, food faddism, or inborn errors of metabolism.

Vitamin deficiency syndromes develop gradually. Symptoms are commonly nonspecific, and the physical examination is rarely helpful in early diagnosis. Most characteristic physical findings are seen late in the course of the syndrome. Other characteristic physical findings, such as glossitis and cheilosis, are seen with deficiencies of many B vitamins. Such abnormalities suggest the presence of a nutritional deficiency but do not indicate which nutrient is deficient.

Despite the relative ease of meeting the recommended daily allowances with a mixed diet, many adults in the United States take vitamin supplements. In fact, syndromes of vitamin excess may be more common than deficiency syndromes, particularly those due to excess of vitamins A, D, and B_6. Most claims for significant health benefits of such supplements, particularly those taken in megadoses, remain unsubstantiated.

Some vitamins can be used efficaciously as drugs. Derivatives of vitamin A are used to treat cystic acne and, more recently, skin wrinkles. Niacin is an effective medication for hyperlipidemia. Vitamin-responsive inborn errors of metabolism also commonly require pharmacologic doses of vitamins.

Thiamine (B_1) Deficiency

Essentials of Diagnosis

- Most common in patients with chronic alcoholism.
- Early symptoms of anorexia, muscle cramps, paresthesias, irritability.
- Advanced syndromes of high output heart failure ("wet beriberi"), peripheral nerve disorders, and Wernicke-Korsakoff syndrome ("dry beriberi").

Clinical Findings

Most thiamine deficiency in the United States is due to alcoholism. Patients with chronic alcoholism may have poor dietary intakes of thiamine and impaired thiamine absorption, metabolism, and storage. Thiamine deficiency is also associated with malabsorption, dialysis, and other causes of chronic protein–calorie undernutrition. Thiamine deficiency can be precipitated in patients with marginal thiamine status with intravenous dextrose solutions.

Early manifestations of thiamine deficiency include anorexia, muscle cramps, paresthesias, and irritability. Advanced deficiency primarily affects the cardiovascular system ("wet beriberi") or the nervous system ("dry beriberi"). Wet beriberi occurs in thiamine deficiency accompanied by severe physical exertion and high carbohydrate intakes. Dry beriberi occurs in thiamine deficiency accompanied by inactivity and low calorie intake.

Wet beriberi is characterized by marked peripheral vasodilation resulting in high-output heart failure with dyspnea, tachycardia, cardiomegaly, and pulmonary and peripheral edema, with warm extremities mimicking cellulitis.

Dry beriberi involves both the peripheral and the central nervous systems. Peripheral nerve involvement is typically a symmetric motor and sensory neuropathy with pain, paresthesias, and loss of reflexes. The legs are affected more than the arms. Central nervous system involvement results in Wernicke–Korsakoff syndrome. Wernicke encephalopathy consists of nystagmus progressing to ophthalmoplegia, truncal ataxia, and confusion. Korsakoff syndrome includes amnesia, confabulation, and impaired learning.

Diagnosis

A variety of biochemical tests are available to assess thiamine deficiency. In most instances, however, the clinical response to empiric thiamine therapy is used to support a diagnosis of thiamine deficiency. The most commonly used and widely available biochemical tests are measurement of erythrocyte transketolase activity and urinary thiamine excretion. A transketolase activity coefficient greater than 15–20% suggests thiamine deficiency.

Treatment

Thiamine deficiency is treated with large parenteral doses of thiamine. Fifty to 100 mg/d is administered intravenously for the first few days, followed by daily oral doses of 5–10 mg/d. All patients should simultaneously receive therapeutic doses of other water-soluble vitamins. Although treatment results in complete resolution in half of patients (one-fourth immediately and another one-fourth over days), the other half obtain only partial resolution or no benefit.

When to Refer

Patients with signs of beriberi or Wernicke-Korsakoff syndrome should be referred to a neurologist.

Thiamine Toxicity

There is no known toxicity of thiamine.

Riboflavin (B_2) Deficiency

Clinical Findings

Riboflavin deficiency almost always occurs in combination with deficiencies of other vitamins. Dietary inadequacy, interactions with a variety of medications, alcoholism, and other causes of protein–calorie undernutrition are the most common causes of riboflavin deficiency.

Manifestations of riboflavin deficiency include cheilosis, angular stomatitis, glossitis, seborrheic dermatitis, weakness, corneal vascularization, and anemia.

Diagnosis

Riboflavin deficiency can be confirmed by measuring the riboflavin-dependent enzyme erythrocyte glutathione reductase. Activity coefficients greater than 1.2–1.3 are suggestive of riboflavin deficiency. Urinary riboflavin excretion and serum levels of plasma and red cell flavins can also be measured.

Treatment

Riboflavin deficiency is usually treated empirically when the diagnosis is suspected. It is easily treated with foods such as meat, fish, and dairy products or with oral preparations of the vitamin. Administration of 5–15 mg/d until clinical findings are resolved is usually adequate. Riboflavin can also be given parenterally, but it is poorly soluble in aqueous solutions.

Said HM et al. Intestinal absorption of water-soluble vitamins: an update. Curr Opin Gastroenterol. 2006 Mar;22(2):140–6. [PMID: 16462170]

Niacin Deficiency

General Considerations

Niacin is a generic term for nicotinic acid and other derivatives with similar nutritional activity. Unlike most other vitamins, niacin can be synthesized from the amino acid tryptophan. Niacin is an essential component of the coenzymes nicotinamide adenine dinucleotide (NAD) and nicotinamide adenine dinucleotide phosphate (NADP), which are involved in many oxidation-reduction reactions. The major food sources of niacin are protein foods containing tryptophan and numerous cereals, vegetables, and dairy products.

Niacin in the form of nicotinic acid is used therapeutically for the treatment of hypercholesterolemia and hypertriglyceridemia. Daily doses of 3–6 g can result in significant reductions in levels of LDL and very-low-density lipoproteins (VLDL) and in elevation of HDL. Niacinamide (the form of niacin usually used to treat niacin deficiency) does not exhibit the lipid-lowering effects of nicotinic acid. Historically, niacin deficiency occurred when corn, which is relatively deficient in both tryptophan and niacin, was the major source of calories. Currently, niacin deficiency is more commonly due to alcoholism and nutrient–drug interactions. Niacin deficiency can also occur in inborn errors of metabolism.

Clinical Findings

As with other B vitamins, the early manifestations of niacin deficiency are nonspecific. Common complaints include anorexia, weakness, irritability, mouth soreness, glossitis, stomatitis, and weight loss. More advanced deficiency results in the classic triad of pellagra: dermatitis, diarrhea, and dementia. The dermatitis is symmetric, involving sun-exposed areas. Skin lesions are dark, dry, and scaling. The dementia begins with insomnia, irritability, and apathy and progresses to confusion, memory loss, hallucinations, and psychosis. The diarrhea can be severe and may result in malabsorption due to atrophy of the intestinal villi. Advanced pellagra can result in death.

Diagnosis

In early deficiency, diagnosis requires a high index of suspicion and attempts at confirmation of niacin deficiency. Niacin metabolites, particularly *N*-methylnicotinamide, can be measured in the urine. Low levels suggest niacin deficiency but may also be found in patients with generalized undernutrition. Serum and red cell levels of NAD and NADP are also low but are similarly nonspecific. In advanced cases, the diagnosis of pellagra can be made on clinical grounds.

Treatment

Niacin deficiency can be effectively treated with oral niacin, usually given as nicotinamide. Doses ranging from 10 mg/d to 150 mg/d have been used without difficulty.

Niacin Toxicity

At the high doses of niacin used to treat hyperlipidemia, side effects are common. These include cutaneous flushing (partially prevented by pretreatment with aspirin, 325 mg/d, and use of extended-release preparations) and gastric irritation. Elevation of liver enzymes, hyperglycemia, and gout are less common untoward effects.

Vitamin B_6 Deficiency

Vitamin B6 deficiency most commonly occurs as a result of interactions with medications—especially isoniazid, cycloserine, penicillamine, and oral contraceptives—or of alcoholism. A number of inborn errors of metabolism and other pyridoxine-responsive syndromes, particularly pyridoxine-responsive anemia, are not clearly due to vitamin deficiency but commonly respond to high doses of the vitamin.

Clinical Findings

Vitamin B6 deficiency results in a clinical syndrome similar to that seen with deficiencies of other B vitamins, including mouth soreness, glossitis, cheilosis, weakness, and irritability. Severe deficiency can result in peripheral neuropathy, anemia, and seizures. Recent studies have suggested a potential relationship of low vitamin B_6 levels and a variety of clinical conditions including cardiovascular diseases, inflammatory diseases, and certain cancers.

Diagnosis

The diagnosis of vitamin B6 deficiency can be confirmed by measurement of pyridoxal phosphate in blood. Normal levels are greater than 50 ng/mL.

Treatment

Vitamin B6 deficiency can be effectively treated with oral vitamin B_6 supplements. Doses of 10–20 mg/d are usually adequate, though some patients taking medications that interfere with pyridoxine metabolism may need doses as high as 100 mg/d. Inborn errors of metabolism and the pyridoxine-responsive syndromes often require doses up to 600 mg/d.

Vitamin B6 should be routinely prescribed for patients receiving medications (such as isoniazid) that interfere with pyridoxine metabolism to prevent vitamin B_6 deficiency. This is particularly true for elderly patients, the urban poor, and alcoholics, who are more likely to have diets marginally adequate in vitamin B_6. Recent clinical trials have shown that vitamin B_6 supplementation, combined with other B vitamins, has no benefit on cardiovascular disease outcomes.

Vitamin B_{12} & Folate

Vitamin B12 (cobalamin) and folate are discussed in Chapter 13: Blood Disorders.

Vitamin C (Ascorbic Acid) Deficiency

Most cases of vitamin C deficiency seen in the United States are due to dietary inadequacy in the urban poor, the elderly, and chronic alcoholics. Patients with chronic illnesses such as cancer and chronic kidney disease and individuals who smoke cigarettes are also at risk.

Clinical Findings

Early manifestations of vitamin C deficiency are nonspecific and include malaise and weakness. In more advanced stages, the typical features of scurvy develop. Manifestations include perifollicular hemorrhages, perifollicular hyperkeratotic papules, petechiae and purpura, splinter hemorrhages, bleeding gums, hemarthroses, and subperiosteal hemorrhages. Periodontal signs do not occur in edentulous patients. Anemia is common, and wound healing is impaired. The late stages of scurvy are characterized by edema, oliguria, neuropathy, intracerebral hemorrhage, and death.

Diagnosis

The diagnosis of advanced scurvy can be made clinically on the basis of the skin lesions in the proper clinical situation. Atraumatic hemarthrosis is also highly suggestive. The diagnosis can be confirmed with decreased plasma ascorbic acid levels, typically below 0.1 mg/dL.

Treatment

Adult scurvy can be treated orally with 300–1000 mg of ascorbic acid per day. Improvement typically occurs within days. Clinical trials have shown that supplemental vitamin C has no benefit on cardiovascular disease or cancer outcomes.

Vitamin C Toxicity

Very large doses of vitamin C can cause gastric irritation, flatulence, or diarrhea. Oxalate kidney stones are of theoretic concern because ascorbic acid is metabolized to oxalate, but stone formation has not been frequently reported. Vitamin C can also confound common diagnostic tests by causing false-negative tests for fecal occult blood and both false-negative and false-positive tests for urine glucose.

Vitamin A Deficiency

Clinical Findings

Vitamin A deficiency is one of the most common vitamin deficiency syndromes, particularly in developing countries. In many such regions, it is the most common cause of blindness. In the United States, vitamin A deficiency is usually due to fat malabsorption syndromes or mineral oil laxative abuse and occurs most commonly in the elderly and urban poor.

Night blindness is the earliest symptom. Dryness of the conjunctiva (xerosis) and the development of small white patches on the conjunctiva (Bitot spots) are early signs. Ulceration and necrosis of the cornea (keratomalacia), perforation, endophthalmitis, and blindness are late manifestations. Xerosis and hyperkeratinization of the skin and loss of taste may also occur.

Diagnosis

Abnormalities of dark adaptation are strongly suggestive of vitamin A deficiency. Serum levels below the normal range of 30–65 mg/dL are commonly seen in advanced deficiency.

Treatment

Night blindness, poor wound healing, and other signs of early deficiency can be effectively treated orally with 30,000 international units of vitamin A daily for 1 week. Advanced deficiency with corneal damage calls for administration of 20,000 international units/kg orally for at least 5 days. The potential antioxidant effects of -carotene can be achieved with supplements of 25,000–50,000 international units of -carotene.

Vitamin A Toxicity

Excess intake of -carotenes (hypercarotenosis) results in staining of the skin a yellow-orange color but is otherwise benign. Skin changes are most marked on the palms and soles, while the scleras remain white, clearly distinguishing hypercarotenosis from jaundice.

Excessive vitamin A (hypervitaminosis A), on the other hand, can be quite toxic. Chronic toxicity usually occurs after ingestion of daily doses of over 50,000 international units/d for more than 3 months. Early manifestations include dry, scaly skin, hair loss, mouth sores, painful hyperostoses, anorexia, and vomiting. More serious findings include hypercalcemia; increased intracranial pressure, with papilledema, headaches, and decreased cognition; and hepatomegaly, occasionally progressing to cirrhosis. Excessive vitamin A has also recently been related to increased risk of hip fracture. Acute toxicity can result from ingestion of massive doses of vitamin A, such as in drug overdoses or consumption of polar bear liver. Manifestations include nausea, vomiting, abdominal pain, headache, papilledema, and lethargy.

The diagnosis can be confirmed by elevations of serum vitamin A levels. The only treatment is withdrawal of vitamin A from the diet. Most symptoms and signs improve rapidly.

Age-Related Eye Disease Study Research Group; SanGiovanni JP et al. The relationship of dietary carotenoid and vitamin A, E, and C intake with age-related macular degeneration in a case-control study: AREDS Report No. 22. Arch Ophthalmol. 2007 Sep;125(9):1225–32. [PMID: 17846363]

Vitamin D

Vitamin D is discussed in Chapter 26: Endocrine Disorders. The major food source of vitamin D is fortified milk, but sunlight on the skin is a prime resource as well.

Vitamin E Deficiency

Clinical Findings

Clinical deficiency of vitamin E is most commonly due to severe malabsorption, the genetic disorder abetalipoproteinemia, or, in children with chronic cholestatic liver disease, biliary atresia or cystic fibrosis. Manifestations of deficiency include areflexia, disturbances of gait, decreased proprioception and vibration, and ophthalmoplegia.

Diagnosis

Plasma vitamin E levels can be measured; normal levels are 0.5–0.7 mg/dL or higher. Since vitamin E is normally transported in lipoproteins, the serum level should be interpreted in relation to circulating lipids.

Treatment

The optimum therapeutic dose of vitamin E has not been clearly defined. Large doses, often administered parenterally, can be used to improve the neurologic complications seen in abetalipoproteinemia and cholestatic liver disease. The potential antioxidant benefits of vitamin E can be achieved with supplements of 100–400 international units/d. Clinical trials of supplemental vitamin E to prevent cardiovascular disease, however, have shown no beneficial effects.

Cook NR et al. A randomized factorial trial of vitamins C and E and beta carotene in the secondary prevention of cardiovascular events in women: results from the Women's Antioxidant Cardiovascular Study. Arch Intern Med. 2007 Aug 13–27;167(15):1610–8. [PMID: 17698683]

Vitamin E Toxicity

Vitamin E has been thought to be the least toxic of the fat-soluble vitamins. Large doses—many times the recommended daily requirement—have been taken for extended periods of time without apparent harm, though nausea, flatulence, and diarrhea have been reported. Clinical trials, however, have suggested an increase in all-cause mortality with high dose (400 international units/d) vitamin E supplements. Large doses of vitamin E can also increase the vitamin K requirement and can result in bleeding in patients taking oral anticoagulants.

Cook NR et al. A randomized factorial trial of vitamins C and E and beta carotene in the secondary prevention of cardiovascular events in women: results from the Women's Antioxidant Cardiovascular Study. Arch Intern Med. 2007 Aug 13-27;167(15):1610–8. [PMID: 17698683]

Opin Lipidol. 2008 Feb;19(1):30–8. [PMID: 18196984]

Vitamin K

Vitamin K is discussed in Chapter 13: Blood Disorders. Vitamin K is synthesized by intestinal bacteria.

Diet Therapy

Specific therapeutic diets can be designed to facilitate the medical management of most common illnesses. In most cases, consultation with a registered dietitian is necessary in order to design and implement major dietary changes. Clinicians should be familiar with the indications for special diets and their basic composition to facilitate patient referrals and to maximize patient compliance. Diet therapy is a difficult process, and not all patients are able to cooperate fully. Requesting the patient to record dietary intake for 3–5 days may provide useful insight into the patient's motivation as well as providing nutrient information about the current diet.

Therapeutic diets can be divided into three groups: (1) diets that alter the consistency of food, (2) diets that restrict or otherwise modify dietary components, and (3) diets that supplement dietary components.

Diets That Alter Consistency

Clear Liquid Diet

This diet provides adequate water, 500–1000 kcal as simple sugar, and some electrolytes. It is fiber free and requires minimal digestion or intestinal motility.

A clear liquid diet is useful for patients with resolving postoperative ileus, acute gastroenteritis, partial intestinal obstruction, and as preparation for diagnostic gastrointestinal procedures. It is commonly used as the first diet for patients who have been taking nothing by mouth for long periods. Because of the low calorie and minimal protein content of the clear liquid diet, it is used only for short periods.

Full Liquid Diet

The full liquid diet provides adequate water and can be designed to provide adequate calories and protein. Vitamins and minerals—especially folic acid, iron, and vitamin B_6—may be inadequate and should be provided in the form of supplements. Dairy products, soups, eggs, and soft cereals are used to supplement clear liquids. Commercial oral supplements can also be incorporated into the diet or used alone.

This diet is low in residue and can be used in many instances instead of the clear liquid diet described above—especially in patients with difficulty in chewing or swallowing, with partial obstructions, or in preparation for some diagnostic procedures. Full liquid diets are commonly used following clear liquid diets to advance diets in patients who have been taking nothing by mouth for long periods.

Soft Diets

Soft diets are designed for patients unable to chew or swallow hard or coarse food. Tender foods are used, and most raw fruits and vegetables and coarse breads and cereals are eliminated. Soft diets are commonly used to assist in progression from full liquid diets to regular diets in postoperative patients, in patients who are too weak or those whose dentition is too poor to handle a general diet, in head and neck surgical patients, in patients with esophageal strictures, and in other patients who have difficulty with chewing or swallowing.

The soft diet can be designed to meet all nutritional requirements.

Diets That Restrict Nutrients

Diets can be designed to restrict (or eliminate) virtually any nutrient or food component. The most commonly used restricted diets are those that limit sodium, fat, and protein. Other restrictive diets include gluten restriction in sprue, potassium and phosphate reduction in chronic kidney disease, and various elimination diets for food allergies.

Sodium-Restricted Diets

Low-sodium diets are useful in the management of hypertension and in conditions in which sodium retention and edema are prominent features, particularly congestive heart failure, chronic liver disease, and chronic kidney disease. Sodium restriction is beneficial with or without diuretic therapy. When used in conjunction with diuretics, sodium restriction allows lower dosage of the diuretic medication and may prevent side effects. Potassium excretion, in particular, is directly related to distal renal tubule sodium delivery, and sodium restriction will decrease diuretic-related potassium losses.

Typical American diets contain a minimum of 4–6 g (175–260 mEq) of sodium per day. A no-added-salt diet contains approximately 3 g (132 mEq) of sodium per day. Further restriction can be achieved with sodium diets of 2 or 1 g/d. Diets with more severe restriction are poorly accepted by patients and are rarely used.

Dietary sodium includes sodium naturally occurring in foods, sodium added during food processing, and sodium added by the consumer during cooking and at the table. About a third of current dietary intake is derived from each. Diets that allow 2000 mg of sodium daily are easiest to design and implement. Such diets generally eliminate added salt, most processed foods, and selected foods with particularly high sodium content. Patients who follow such diets for 2–3 months lose their craving for salty foods and can often continue to restrict their sodium intake indefinitely. Many patients with mild hypertension will achieve significant reductions in blood pressure (approximately 5 mm Hg diastolic) with this degree of sodium restriction. Other patients require more severe sodium restriction (approximately 1000 mg of sodium per day) for reduction in blood pressure.

Diets allowing 1000 mg of sodium require further restriction of commonly eaten foods. Special "low-sodium" products are now available to facilitate such diets. These diets are difficult for most people to follow and are generally reserved for hospitalized patients and highly motivated outpatients—most commonly those with severe liver disease and ascites.

Fat-Restricted Diets

Traditional fat-restricted diets are useful in the treatment of fat malabsorption syndromes. Such diets will improve the symptoms of diarrhea with steatorrhea independently of the primary physiologic abnormality by limiting the quantity of fatty acids that reach the colon. The degree of fat restriction necessary to control symptoms must be individualized. Patients with severe malabsorption can be limited to 40–60 g of fat per day. Diets containing 60–80 g of fat per day can be designed for patients with less severe abnormalities.

In general, fat-restricted diets require broiling, baking, or boiling meat and fish; discarding the skin of poultry and fish and using those foods as the main protein source; using nonfat dairy products; and avoiding desserts, sauces, and gravies.

Low-Cholesterol, Low-Saturated-Fat Diets

Fat-restricted diets that specifically restrict saturated fats and dietary cholesterol are the mainstay of dietary treatment of hyperlipidemia (see Chapter 28: Lipid Disorders). Similar diets are recommended also for diabetes (see Chapter 27: Diabetes Mellitus & Hypoglycemia) and for the prevention of coronary artery disease (see Chapter 10: Heart Disease). Current recommendations for the prevention of cancer by dietary modification also include fat restriction. The large Women's Health Initiative Dietary Modification Trial, however, did not show any significant benefit of a low-fat diet on weight control or prevention of cardiovascular disease or cancer.

The aim of these diets is to restrict total fat to less than 30% of calories and to achieve a normal body weight by caloric restriction and increased physical activity. Saturated fat is restricted to 7% of calories and dietary cholesterol to 200 mg/d. Saturated fat can be replaced either with complex carbohydrates or, if energy balance permits, with monounsaturated fats. Saturated fat, total fat, and dietary cholesterol can be restricted further, but studies suggest that more extreme restriction offers little further advantage in overall modification of serum lipids. Cholesterol-lowering diets can be further augmented with the addition of plant stanols and sterols and with soluble dietary fiber.

Protein-Restricted Diets

Protein-restricted diets are most commonly used in patients with hepatic encephalopathy due to chronic liver disease and in patients with advanced chronic kidney disease to slow the progression of early disease and to decrease symptoms of uremia in more severe disease. Patients with selected inborn errors of amino acid metabolism and other abnormalities resulting in hyperammonemia also require restriction of protein or of specific amino acids.

Protein restriction is intended to limit the production of nitrogenous waste products. Energy intake must be adequate to facilitate the efficient use of dietary protein. Proteins must be of high biologic value and be provided in sufficient quantity to meet minimal requirements. For most patients, the diet should contain at least 0.6 g/kg/d of protein. Patients with encephalopathy who do not respond to this degree of restriction are unlikely to respond to more severe restriction.

Diets That Supplement Nutrients

High-Fiber Diet

Dietary fiber is a diverse group of plant constituents that is resistant to digestion by the human digestive tract. Typical American diets contain about 5–10 g of dietary fiber per day. Epidemiologic evidence has suggested that populations consuming greater quantities of fiber have a lower incidence of certain gastrointestinal disorders, including diverticulitis and colon cancer. Most authorities currently recommend higher intakes of dietary fiber for health maintenance.

Diets high in dietary fiber (20–35 g/d) are also commonly used in the management of a variety of gastrointestinal disorders, particularly irritable bowel syndrome and recurrent diverticulitis. Diets high in fiber may also be useful to reduce blood sugar in patients with diabetes and to reduce cholesterol levels in patients with hypercholesterolemia. Such diets include greater intakes of fresh fruits and vegetables, whole grains, legumes and seeds, and bran products. For some patients, the addition of psyllium seed (2 tsp per day) or natural bran (one-half cup per day) may be preferable.

High-Potassium Diets

Potassium-supplemented diets are used most commonly to compensate for potassium losses caused by diuretics.

Although potassium losses can be partially prevented by using lower doses of diuretics, concurrent sodium restriction, and potassium-sparing diuretics, some patients require additional potassium to prevent hypokalemia. High-potassium diets may also have a direct antihypertensive effect. Typical American diets contain about 3 g (80 mEq) of potassium per day. High-potassium diets commonly contain 4.5–7 g (120–180 mEq) of potassium per day.

Most fruits, vegetables, and their juices contain high concentrations of potassium. Supplemental potassium can also be provided with potassium-containing salt substitutes (up to 20 mEq in one-quarter tsp) or as potassium chloride in solution or capsules, but this is rarely necessary if the above measures are followed to prevent potassium losses and supplement dietary potassium.

High-Calcium Diets

Additional intakes of dietary calcium have been recommended for the prevention of postmenopausal osteoporosis, the prevention and treatment of hypertension, and the prevention of colon cancer. The recent Women's Health Initiative, however, suggested that calcium and vitamin D supplementation did not prevent fractures or colon cancer. Nonetheless, many authorities recommend intakes of 1 g of calcium per day for most adults and 1.5 g/d for postmenopausal women. Average American daily intakes are approximately 700 mg/d.

Dairy products are the primary dietary sources of calcium in the United States. Patients with lactose intolerance who cannot tolerate liquid dairy products may be able to tolerate nonliquid products such as cheese and yogurt. Leafy green vegetables and canned fish with bones also contain high concentrations of calcium, although the latter is also high in sodium.

Nutritional Support

Nutritional support is the provision of nutrients to patients who cannot meet their nutritional requirements by eating standard diets. Nutrients may be delivered enterally, using oral nutritional supplements, nasogastric and nasoduodenal feeding tubes, and tube enterostomies, or parenterally, using lines or catheters placed in peripheral or central veins, respectively. Current nutritional support techniques permit adequate nutrient delivery to most patients. Nutrition support should be utilized, however, only if it is likely to improve the patient's clinical outcome. The financial costs and risks of side effects must be balanced against the potential advantages of improved nutritional status in each clinical situation.

Indications for Nutritional Support

The precise indications for nutritional support remain controversial. Most authorities agree that nutritional support is indicated for at least four groups of adult patients: (1) those with inadequate bowel syndromes, (2) those with severe prolonged hypercatabolic states (eg, due to extensive burns, multiple trauma, mechanical ventilation), (3) those requiring prolonged therapeutic bowel rest, and (4) those with severe protein–calorie undernutrition with a treatable disease who have sustained a loss of over 25% of body weight.

It has been difficult to prove the efficacy of nutritional support in the treatment of most other conditions. In most cases it has not been possible to show a clear advantage of treatment by means of nutritional support over treatment without such support.

The American Society for Parenteral and Enteral Nutrition (ASPEN) has published recommendations for the rational use of nutritional support. The recommendations emphasize the need to individualize the decision to begin nutritional support, weighing the risks and costs against the benefits to each patient. They also reinforce the need to identify high-risk malnourished patients by nutritional assessment.

Nutritional Support Methods

Selection of the most appropriate nutritional support method involves consideration of gastrointestinal function, the anticipated duration of nutritional support, and the ability of each method to meet the patient's nutritional requirements. The method chosen should meet the patient's nutritional needs with the lowest risk and lowest cost possible. For most patients, enteral feeding is safer and cheaper and offers significant physiologic advantages. An algorithm for selection of the most appropriate nutritional support method is presented in Figure 29–1.

Figure 29–1

Nutritional support method decision tree.

Prior to initiating specialized enteral nutritional support, efforts should be made to supplement food intake.

Attention to patient preferences, timing of meals and diagnostic procedures and use of medications, and the use of foods brought to the hospital by family and friends can often increase oral intake. Patients unable to eat enough at regular mealtimes to meet nutritional requirements can be given **oral supplements** as snacks or to replace low-calorie beverages. Oral supplements of differing nutritional composition are available for the purpose of individualizing the diet in accordance with specific clinical requirements (see below). Fiber and lactose content, caloric density, protein level, and amino acid profiles can all be modified as necessary.

Patients unable to take adequate oral nutrients who have functioning gastrointestinal tracts and who meet the criteria for nutritional support are candidates for **tube feedings**. Small-bore feeding tubes are placed via the nose into the stomach or duodenum. Patients able to sit up in bed who can protect their airways can be fed into the stomach. Because of the increased risk of aspiration, patients who cannot adequately protect their airways should be fed nasoduodenally. Feeding tubes can usually be passed into the duodenum by leaving an extra length of tubing in the stomach and placing the patient in the right decubitus position. Metoclopramide, 10 mg intravenously, can be given 20 minutes prior to insertion and continued every 6 hours thereafter to facilitate passage through the pylorus. Occasionally patients will require fluoroscopic or endoscopic guidance to insert the tube distal to the pylorus. Placement of nasogastric and, particularly, nasoduodenal tubes should be confirmed radiographically before delivery of feeding solutions.

Feeding tubes can also be placed directly into the gastrointestinal tract using **tube enterostomies.** Most tube enterostomies are placed in patients who require long-term enteral nutritional support. Gastrostomies have the advantage of allowing bolus feedings, while jejunostomies require continuous infusions. Gastrostomies—like nasogastric feeding—should be used only in patients at low risk for aspiration. Gastrostomies can also be placed percutaneously with the aid of endoscopy. These tubes can then be advanced to jejunostomies. Tube enterostomies can also be placed surgically.

Patients who require nutritional support but whose gastrointestinal tracts are nonfunctional should receive **parenteral nutritional support**. Most patients receive parenteral feedings via a central vein—most commonly the subclavian vein. Peripheral veins can be used in some patients, but because of the high osmolality of parenteral solutions this is rarely tolerated for more than a few weeks.

Peripheral vein nutritional support is most commonly used in patients with nonfunctioning gastrointestinal tracts who require immediate support but whose clinical status is expected to improve within 1–2 weeks, allowing enteral feeding. Peripheral vein nutritional support is administered via standard intravenous lines. Solutions should always include lipid and dextrose in combination with amino acids to provide adequate nonprotein calories. Serious side effects are infrequent, but there is a high incidence of phlebitis and infiltration of intravenous lines.

Central vein nutritional support is delivered via intravenous catheters placed percutaneously using aseptic technique. Proper placement in the superior vena cava is documented radiographically before the solution is infused. Catheters must be carefully maintained by experienced nursing personnel and used solely for nutritional support to prevent infection and other catheter-related complications.

Nutritional Requirements

Each patient's nutritional requirements should be determined independently of the method of nutritional support. In most situations, solutions of equal nutrient value can be designed for delivery via enteral and parenteral routes, but differences in absorption must be considered. A complete nutritional support solution must contain water, energy, amino acids, electrolytes, vitamins, minerals, and essential fatty acids.

Water

For most patients, water requirements can be calculated by allowing 1500 mL for the first 20 kg of body weight plus 20 mL for every kilogram over 20. Additional losses should be replaced as they occur. For average-sized adult patients, fluid needs are about 30–35 mL/kg, or approximately 1 mL/kcal of energy required (see below).

Energy

Energy requirements can be estimated by one of three methods: (1) by using standard equations to calculate BEE plus additional calories for activity and illness, (2) by applying a simple calculation based on calories per kilogram of body weight, or (3) by measuring energy expenditure with indirect calorimetry.

BEE can be estimated by the **Harris–Benedict equation**: for men, BEE = 666 + (13.7 x weight in kg) + (5 x height in cm) – (6.8 x age in years). For women, BEE = 655 + (9.5 x weight in kg) + (1.8 x height in cm) – (4.7 x age in years). For undernourished patients, actual body weight should be used; for obese patients, ideal body weight should be used. For most patients, an additional 20–50% of BEE is administered as nonprotein calories to accommodate energy expenditures during activity or relating to the illness. Occasional patients are noted to have energy expenditures greater than 150% of BEE.

Energy requirements can be estimated also by multiplying actual body weight in kilograms (for obese patients, ideal body weight) by 30–35 kcal.

Both of these methods provide imprecise estimates of actual energy expenditures, especially for the markedly underweight, overweight, and critically ill patient. Studies using indirect calorimetry have demonstrated that as many as 30–40% of patients will have measured expenditures 10% above or below estimated values. For accurate determination of energy expenditure, indirect calorimetry should be used.

Protein

Protein and energy requirements are closely related. If adequate calories are provided, most patients can be given 0.8–1.2 g of protein per kilogram per day. Patients undergoing moderate to severe stress should receive up to 1.5 g/kg/d. As in the case of energy requirements, actual weights should be used for normal and underweight patients and ideal weights for patients with significant obesity.

Patients who are receiving protein without adequate calories will catabolize protein for energy rather than utilizing it for protein synthesis. Thus, when energy intake is low, excess protein is needed for nitrogen balance. If both energy and protein intakes are low, extra energy will have a more significant positive effect on nitrogen balance than extra protein.

Electrolytes & Minerals

Requirements for sodium, potassium, and chloride vary widely. Most patients require 45–145 mEq/d of each. The actual requirement in individual patients will depend on the patient's cardiovascular, renal, endocrine, and gastrointestinal status as well as measurements of serum concentration.

Patients receiving enteral nutritional support should receive adequate vitamins and minerals according to the recommended daily allowances. Most premixed enteral solutions provide adequate vitamins and minerals as long as adequate calories are administered.

Patients receiving parenteral nutritional support require smaller amounts of minerals: calcium, 10–15 mEq/d; phosphorus, 15–20 mEq per 1000 nonprotein calories; and magnesium, 16–24 mEq/d. Most patients receiving nutritional support do not require supplemental iron because body stores are adequate. Iron nutrition should be monitored closely by following the hemoglobin concentration, mean corpuscular volume, and iron studies. Parenteral administration of iron is associated with a number of adverse effects and should be reserved for iron-deficient patients unable to take oral iron.

Patients receiving parenteral nutritional support should be given the trace elements zinc (about 5 mg/d) and copper (about 2 mg/d). Patients with diarrhea will require additional zinc to replace fecal losses. Additional trace elements—especially chromium, manganese, and selenium—are provided to patients receiving long-term parenteral nutrition.

Parenteral vitamins are provided daily. Standardized multivitamin solutions are currently available to provide adequate quantities of vitamins A, B_{12}, C, D, E, thiamine, riboflavin, niacin, pantothenic acid, pyridoxine, folic acid, and biotin. Vitamin K is not given routinely but administered when the prothrombin time becomes abnormal.

Essential Fatty Acids

Patients receiving nutritional support should be given 2–4% of their total calories as linoleic acid to prevent essential fatty acid deficiency. Most prepared enteral solutions contain adequate linoleic acid. Patients receiving parenteral nutrition should be given at least 250 mL of a 20% intravenous fat (emulsified soybean or safflower oil) about two or three times a week. Intravenous fat can also be used as an energy source in place of dextrose.

Enteral Nutritional Support Solutions

Most patients who require enteral nutritional support can be given commercially prepared enteral solutions (Table 29–1). Nutritionally complete solutions have been designed to provide adequate proportions of water, energy, protein, and micronutrients. Nutritionally incomplete solutions are also available to provide specific macronutrients (eg, protein, carbohydrate, and fat) to supplement complete solutions for patients with unusual requirements or to design solutions that are not available commercially.

Table 29–1. Enteral solutions.
Complete
Blenderized (eg, Compleat Regular, Compleat Modified,[1] Vitaneed[1])
Whole protein, lactose-containing (eg, Mentene, Carnation and Delmark Instant Breakfast, Forta Shake)
Whole protein, lactose-free, low-residue:
1 kcal/mL (eg, Ensure, Isocal, Osmolite, Nutren 1.0,[1] Nutrilan, Isolan,[1] Sustacal, Resource)
1.5 kcal/mL (eg, Ensure Plus, Sustacal HC, Comply, Nutren 1.5, Resource Plus)
2 kcal/mL (eg, Isocal HCN, Magnacal, TwoCal HN)

High-nitrogen: > 15% total calories from protein (eg, Ensure HN, Attain,[1] Osmolite HN,[1] Replete, Entrition HN,[1] Isolan,[1] Isocal HN,[1] Sustacal HC, Isosource HN,[1] Ultralan)
Whole protein, lactose-free, high-residue:
1 kcal/mL (eg, Jevity,[1] Profiber,[1] Nutren 1.0 with fiber,[1] Fiberian,[1] Sustacal with fiber, Ultracal,[1] Ensure with fiber, Fibersource)
Chemically defined peptide- or amino acid-based (eg, Accupep HPF, Criticare HN, Peptamen,[1] Reabfin, Vital HN, AlitraQ, Tolerex, Vivonex TEN)
"Disease-specific" formulas
Advanced chronic kidney disease: with essential amino acids (eg, Amin-Aid, Travasorb Renal, Aminess)
Malabsorption: with medium-chain triglycerides (eg, Portagen,[1] Travasorb MCT)
Respiratory failure: with > 50% calories from fat (eg, Pulmocare, NutriVent)
Hepatic encephalopathy: with high amounts of branched-chain amino acids (eg, Hepatic-Acid II, Travasorb Hepatic)

Incomplete (modular)
Protein (eg, Nutrisource Protein, Promed, Propac)
Carbohydrate (eg, Nutrisource Carbohydrate, Polycose, Sumacal)
Fat (eg, MCT Oil, Microlipid, Nutrisource Lipid)
Vitamins (eg, Nutrisource Vitamins)
Minerals (eg, Nutrisource Minerals)

[1] Isotonic.

Nutritionally complete solutions are characterized as follows: (1) by osmolality (isotonic or hypertonic), (2) by lactose content (present or absent), (3) by the molecular form of the protein component (intact proteins; peptides or amino acids), (4) by the quantity of protein and calories provided, and (5) by fiber content (present or absent). For most patients, isotonic solutions containing no lactose or fiber are preferable. Such solutions generally contain moderate amounts of fat and intact protein. Most commercial isotonic solutions contain 1000 kcal and about 37–45 g of protein per liter.

Solutions containing hydrolyzed proteins or crystalline amino acids and with no significant fat content are called elemental solutions, since macronutrients are provided in their most "elemental" form. These solutions have been designed for patients with malabsorption, particularly pancreatic insufficiency and limited fat absorption. Elemental diets are extremely hypertonic and often result in more severe diarrhea. Their use should be limited to patients who cannot tolerate isotonic solutions.

Although formulas have been designed for specific clinical situations—solutions containing primarily essential amino acids (for advanced chronic kidney disease), medium-chain triglycerides (for fat malabsorption), more fat (for respiratory failure and CO_2 retention), and more branched-chain amino acids (for hepatic encephalopathy and severe trauma)—they have not been shown to be superior to standard formulas for most patients.

Enteral solutions should be administered via continuous infusion, preferably with an infusion pump. Isotonic feedings should be started at full strength at about 25–33% of the estimated final infusion rate. Feedings can be advanced by similar amounts every 12 hours as tolerated. Hypertonic feedings should be started at half strength. The strength and the rate can then be advanced every 6 hours as tolerated.

Complications of Enteral Nutritional Support

Minor complications of tube feedings occur in 10–15% of patients. Gastrointestinal complications include diarrhea (most common), inadequate gastric emptying, emesis, esophagitis, and occasionally gastrointestinal bleeding. Diarrhea associated with tube feeding may be due to intolerance to the osmotic load or to one of the macronutrients (eg, fat, lactose) in the solution. Patients being fed in this way may also have diarrhea from other causes (as side effects of antibiotics or other drugs, associated with infection, etc), and these possibilities should always be investigated in appropriate circumstances.

Mechanical complications of tube feedings are potentially the most serious. Of particular importance is aspiration. All patients receiving nasogastric tube feedings are at risk for this life-threatening complication. Limiting nasogastric feedings to those patients who can adequately protect their airway and careful monitoring of patients being fed by tube should limit these serious complications to 1–2% of cases. Minor mechanical complications are common and include tube obstruction and dislodgment.

Metabolic complications during enteral nutritional support are common but in most cases are easily managed. The most important problem is hypernatremic dehydration, most commonly seen in elderly patients given excessive protein intake who are unable to respond to thirst. Abnormalities of potassium, glucose, and acid–base balance may also occur.

Parenteral Nutritional Support Solutions

Parenteral nutritional support solutions can be designed to deliver adequate nutrients to most patients. The basic parenteral solution is composed of dextrose, amino acids, and water. Electrolytes, minerals, trace elements, vitamins, and medications can also be added. Most commercial solutions contain the monohydrate form of dextrose that provides 3.4 kcal/g. Crystalline amino acids are available in a variety of concentrations, so that a broad range of solutions can be made up that will contain specific amounts of dextrose and amino acids as required.

Typical solutions for central vein nutritional support contain 25–35% dextrose and 2.75–6% amino acids depending upon the patient's estimated nutrient and water requirements. These solutions typically have osmolalities in excess of 1800 mosm/L and require infusion into a central vein. A typical formula for patients without organ failure is shown in Table 29–2.

Table 29–2. Typical parenteral nutrition solution (for stable patients without organ failure).

Dextrose (3.4 kcal/g)	25%
Amino acids (4 kcal/g)	6%
Na^+	50 mEq/L

K^+	40 mEq/L
Ca^{2+}	5 mEq/L
Mg^{2+}	8 mEq/L
Cl^-	60 mEq/L
P	12 mEq/L
Acetate	Balance
MVI-12 (vitamins)	10 mL/d
MTE (trace elements)	5 mL/d
Fat emulsion 20%	250 mL five times a week
Typical rate	Day 1: 30 mL/h
	Day 2: 60 mL/h
By day 2, solution provides:	Calories: 1925 kcal total
	Protein: 86 g
	Fat: 19% of total kcal
	Fluid: 1690 mL

Solutions with lower osmolalities can also be designed for infusion into peripheral veins. Typical solutions for peripheral infusion contain 5–10% dextrose and 2.75–

4.25% amino acids. These solutions have osmolalities between 800 and 1200 mosm/L and result in a high incidence of thrombophlebitis and line infiltration. These solutions will provide adequate protein for most patients but inadequate energy. Additional energy must be provided in the form of emulsified soybean or safflower oil. Such intravenous fat solutions are currently available in 10% and 25% solutions providing 1.1 and 2.2 kcal/mL, respectively. Intravenous fat solutions are isosmotic and well tolerated by peripheral veins. Typical patients are given 200–500 mL of a 20% solution each day. As much as 60% of total calories can be administered in this manner.

Intravenous fat can also be provided to patients receiving central vein nutritional support. In this instance, dextrose concentrations should be decreased to provide a fixed concentration of energy. Intravenous fat has been shown to be equivalent to intravenous dextrose in providing energy to spare protein. Intravenous fat is associated with less glucose intolerance, less production of carbon dioxide, and less fatty infiltration of the liver and has been increasingly utilized in patients with hyperglycemia, respiratory failure, and liver disease. Intravenous fat has also been increasingly used in patients with large estimated energy requirements. Recent studies suggest that the maximum glucose utilization rate is approximately 5–7 mg/min/kg. Patients who require additional calories can be given them as fat to prevent excess administration of dextrose. Intravenous fat can also be used to prevent essential fatty acid deficiency. The optimal ratio of carbohydrate and fat in parenteral nutritional support has not been determined.

Infusion of parenteral solutions should be started slowly to prevent hyperglycemia and other metabolic complications. Typical solutions are given initially at a rate of 50 mL/h and advanced by about the same amount every 24 hours until the desired final rate is reached.

Complications of Parenteral Nutritional Support

Complications of central vein nutritional support occur in up to 50% of patients. Although most are minor and easily managed, significant complications will develop in about 5% of patients. Complications of central vein nutritional support can be divided into catheter-related complications and metabolic complications.

Catheter-related complications can occur during insertion or while the catheter is in place. Pneumothorax, hemothorax, arterial laceration, air emboli, and brachial plexus injury can occur during catheter placement. The incidence of these complications is inversely related to the experience of the physician performing the procedure but will occur in at least 1–2% of cases even in major medical centers. Each catheter placement should be documented by chest radiograph prior to initiation of nutritional support.

Catheter thrombosis and catheter-related sepsis are the most important complications of indwelling catheters. Patients with indwelling central vein catheters in whom fever develops without an apparent source should have their lines changed over a wire or removed immediately, the tip quantitatively cultured, and antibiotics begun empirically. Quantitative tip cultures and blood cultures will help guide further antibiotic therapy. Catheter-related sepsis occurs in 2–3% of patients even if maximal efforts are made to prevent infection.

Metabolic complications of central vein nutritional support occur in over 50% of patients (Table 29–3). Most are minor and easily managed, and termination of support is seldom necessary.

Table 29–3. Metabolic complications of parenteral nutritional support.

Complication	**Common Causes**	**Possible Solutions**
Hyperglycemia	Too rapid infusion of dextrose, "stress,"	Decrease glucose infusion; insulin;

	corticosteroids	replacement of dextrose with fat
Hyperosmolar nonketotic dehydration	Severe, undetected hyperglycemia	Insulin, hydration, potassium
Hyperchloremic metabolic acidosis	High chloride administration	Decrease chloride
Azotemia	Excessive protein administration	Decrease amino acid concentration
Hyperphosphatemia, hypokalemia, hypomagnesemia	Extracellular to intracellular shifting with refeeding	Increase solution concentration
Liver enzyme abnormalities	Lipid trapping in hepatocytes, fatty liver	Decrease dextrose
Acalculous cholecystitis	Biliary stasis	Oral fat
Zinc deficiency	Diarrhea, small bowel fistulas	Increase concentration
Copper deficiency	Biliary fistulas	Increase concentration

Patient Monitoring During Nutritional Support

Every patient receiving enteral or parenteral nutritional support should be monitored closely. Formal nutritional support teams composed of a physician, a nurse, a dietitian, and a pharmacist have been shown to decrease the rate of complications.

Patients should be monitored both for the adequacy of treatment and to prevent complications or detect them early when they occur. Because estimates of nutritional requirements are imprecise, frequent reassessment is necessary. Daily intakes should be recorded and compared with estimated requirements. Body weight, hydration status, and overall clinical status should be followed. Patients who do not appear to be responding as anticipated can be evaluated for nitrogen balance by means of the following equation:

Patients with positive nitrogen balances can be continued on their current regimens; patients with negative balances should receive moderate increases in calorie and protein intake and then be reassessed. Monitoring for metabolic complications includes daily measurements of electrolytes; serum glucose, phosphorus, magnesium, calcium, and creatinine; and BUN until the patient is stabilized. Once the patient is stabilized, electrolytes, phosphorus, calcium, magnesium, and glucose should be obtained at least twice weekly. Red blood cell folate, zinc, and copper should be checked at least once a month.

Penicillins

The penicillins share a common chemical nucleus (6-aminopenicillanic acid) that contains a -lactam ring essential to their biologic activity.

Antimicrobial Action & Resistance

The initial step in penicillin action is the binding of the drug to receptors—penicillin-binding proteins. The proteins of different organisms vary in number and in affinity for a given drug. After penicillins have attached to receptors, peptidoglycan synthesis is inhibited due to blockage of transpeptidation. The final bactericidal action is the removal of an inhibitor of the autolytic enzymes in the cell wall, which activates the enzymes and results in cell lysis. Organisms that produce -lactamases (penicillinases) are resistant to some penicillins because the -lactam ring is broken and the drug is inactivated. Only organisms actively synthesizing peptidoglycan (in the process of multiplication) are susceptible to -lactam antibiotics. Nonmultiplying organisms or those lacking cell walls are not susceptible.

Microbial resistance to penicillins is caused by four factors: (1) Production of -lactamases, eg, by staphylococci, gonococci, *Haemophilus* species, and coliform organisms, including extended-spectrum -lactamase (ESBL)–producing bacteria; (2) lack of penicillin-binding proteins or decreased affinity of penicillin-binding protein for -lactam antibiotic receptors (eg, resistant pneumococci, methicillin-resistant staphylococci, enterococci) or impermeability of cell envelope; (3) failure of activation of autolytic enzymes in the cell wall—"tolerance," eg, in staphylococci, group B streptococci; and (4) cell wall-deficient (L) forms or mycoplasmas, which do not synthesize peptidoglycans.

Natural Penicillins

The natural penicillins include penicillin G for parenteral administration (aqueous crystalline or benzathine penicillin G) or for oral administration (penicillin G and phenoxymethyl penicillin [penicillin V]). They are most active against gram-positive organisms and are susceptible to hydrolysis by -lactamases. They are used (1) for infections caused by susceptible and moderately susceptible pneumococci, depending on the site of infection (however, up to 30–35% of strains now demonstrate intermediate- or high-level resistance to penicillin); (2) streptococci (including anaerobic streptococci); (3) meningococci; (4) non– -lactamase-producing staphylococci; (5) *Treponema pallidum* and other spirochetes; (6) *Propionibacterium acnes* and other gram-positive rods; (7) non-difficile clostridia; (8) actinomyces; and (9) most gram-positive anaerobes. See Table 30–4.

Pharmacokinetics & Administration

After parenteral administration, penicillin has wide extracellular distribution. Lower levels are present in the eye, prostate, and central nervous system. However, with inflammation of the meninges and with appropriate dosing, adequate penetration into the cerebrospinal fluid takes place.

Because benzathine penicillin allows for extended release of penicillin, continuous blood and tissue levels are achieved.

Phenoxymethyl penicillin (penicillin V) is the oral penicillin of choice because of its superior bioavailability. Penicillin is renally eliminated; however, the majority is cleared by tubular secretion.

Clinical Uses

Most infections due to susceptible organisms respond to aqueous penicillin G in daily doses of 1–2 million units administered intravenously every 4–6 hours. For life-threatening infections (meningitis, endocarditis), increased daily doses (18–24 million units intravenously) are required.

Penicillin V is indicated in minor infections such as streptococcal pharyngitis and cellulitis. Syphilis requires weekly injections of benzathine penicillin, 2.4 million units intramuscularly for 1–3 weeks, depending on the stage of the disease (see Table 30–10).

Extended-Spectrum Penicillins

The extended-spectrum group of penicillins includes the aminopenicillins: ampicillin and amoxicillin and the ureidopenicillin piperacillin (available only in combination with the -lactamase inhibitor tazobactam). These drugs are susceptible to destruction by staphylococcal (and other) -lactamases. While this group of penicillins is more active against certain gram-negative rods, they have approximately the same activity as natural penicillins against gram-positive bacteria. With the availability of -lactamase inhibitor combinations, such as ampicillin-sulbactam and piperacillin-tazobactam, ticarcillin and piperacillin are no longer marketed in the United States.

Antimicrobial Activity

Ampicillin and amoxicillin are active against most strains of *Proteus mirabilis*, *Listeria*, and non– -lactamase-producing strains of *Haemophilus influenzae* but are inactive against most gram-negative pathogens. Both drugs are effective against penicillin-susceptible pneumococcus and *Enterococcus faecalis;* however, ampicillin-resistant *E faecalis* has emerged.

Ticarcillin, piperacillin, and the -lactam/ -lactamase inhibitor ticarcillin-clavulanate are no longer marketed. However, considering that piperacillin-tazobactam is commercially available, it is important to know the spectrum of activity of piperacillin.

Piperacillin is active against *Pseudomonas aeruginosa* and *Klebsiella*. Similar to ampicillin, piperacillin is active against *E faecalis* and pneumococci. The extended-spectrum penicillins inhibit many but not all anaerobes. Ampicillin and amoxicillin are not active against -lactamase-producing strains of *Bacteroides fragilis*—in contrast to piperacillin, which is active against many of these isolates.

Pharmacokinetics & Administration

Ampicillin can be given orally or parenterally. Amoxicillin is preferable to ampicillin in the oral treatment of infection because of its improved oral bioavailability and less frequent dosage frequency. An extended-release amoxicillin tablet (Moxatag) has been approved for once-daily use for streptococcal pharyngitis in children < 12 years.

Piperacillin (in combination with tazobactam) is given intravenously and increased doses (200–300 mg/kg/d) are required for treatment of infections due to *P aeruginosa*.

See Table 30–11 for a summary of dosage adjustments that are required in kidney disease.

Clinical Uses

Amoxicillin is given orally for minor infections, such as exacerbations of chronic bronchitis, sinusitis, or otitis. Ampicillin is administered intravenously for pneumonia, meningitis, bacteremia, or endocarditis.

Amoxicillin is also used as prophylaxis for endocarditis. Because of the increased serum and respiratory secretion levels, this agent is valuable in the treatment of susceptible and moderately penicillin-susceptible pneumococcus. In general, if amoxicillin levels remain above the minimum inhibitory concentration (MIC) of intermediately susceptible pneumococcus for more than 40% of the dosing interval (which can be achieved with a dose of 40 mg/kg/d in adults), bacteriologic cure rates are optimal. An ambulatory 3-day course of amoxicillin, 80–90 mg/kg/d in two doses, has been found to be equivalent to parenteral antibacterials in the treatment of community-acquired pneumonia.

Penicillins Combined with -Lactamase Inhibitors

The addition of -lactamase inhibitors (clavulanic acid, sulbactam, tazobactam) prevents inactivation of the parent penicillin by bacterial -lactamases. Products available are Augmentin (amoxicillin, 250 mg, 500 mg, or 875 mg, plus 125 mg of clavulanic acid); Augmentin XR (amoxicillin 1 g plus 62.5 mg of clavulanic acid); Unasyn (ampicillin 1 g plus sulbactam 0.5 g, and ampicillin 3 g plus sulbactam 1 g); and Zosyn (piperacillin 3 g plus tazobactam 0.375 g, and piperacillin 4 g plus tazobactam 0.5 g). Augmentin is given orally and the others intravenously. In general, the -lactamase inhibitors effectively inactivate -lactamases produced by *Staphylococcus aureus, H influenzae, Moraxella catarrhalis*, and *B fragilis*. In contrast, the -lactamase inhibitors are variably and unpredictably effective against -lactamases produced by certain aerobic gram-negative bacilli, such as *Enterobacter*. Of the available parenteral drugs, Zosyn has the broadest spectrum of activity. Like Unasyn, Zosyn is active against ampicillin-susceptible enterococci. It has greater in vitro activity against *P aeruginosa*, *Serratia*, and *Klebsiella* species when compared with Augmentin or Unasyn. While these agents are sometimes active in vitro, they are less useful clinically in the treatment of ESBL–producing organisms.

Augmentin, because of its increased cost, compared to amoxicillin, and gastrointestinal intolerance, is limited to the treatment of refractory cases of sinusitis and otitis and prophylaxis of infections resulting from animal and human bites. The roles of Unasyn and Zosyn include the treatment of polymicrobial infections such as peritonitis from a ruptured viscus, osteomyelitis in a diabetic patient, or traumatic osteomyelitis.

As discussed previously, when Zosyn is used to treat *Pseudomonas* infections, dosages of 200–300 mg/kg/d of the piperacillin component are used.

Piperacillin-tazobactam treatment of pseudomonal isolates with reduced piperacillin-tazobactam susceptibility may be associated with increased mortality. Nonpseudomonal infection can be treated with lower doses (100–200 mg/kg/d).

Antistaphylococcal Penicillins

Oxacillin, cloxacillin, dicloxacillin, and nafcillin are relatively resistant to destruction by -lactamases produced by staphylococci. They are less active than natural penicillins against nonstaphylococcal gram-positive bacteria; however, they are still adequate in certain streptococcal infections, including those due to group A streptococci in skin and soft tissue infections.

The primary route of clearance of the above agents is nonrenal—thus, no dosage adjustment is needed in kidney disease.

Toxicity & Adverse Events

All penicillins are associated with allergic reactions, ranging from serious IgE-mediated reactions, including anaphylaxis and bronchospasm, to non–IgE-mediated reactions, such as macular popular rash. All penicillins in excessive doses, particularly in kidney disease, have been associated with seizures.

Of the oral penicillins, amoxicillin-clavulanate is most commonly associated with diarrhea. Nafcillin administered at high doses is associated with a modest leukopenia. Oxacillin may cause a higher incidence of liver toxicity than other agents in this class. High doses of penicillins, particularly piperacillin (with tazobactam), inhibit platelet aggregation and produce hypokalemia due to binding of potassium in the kidney.

Infect Dis. 2008 Mar 15;46(6):862–7. [PMID: 18279040]

Cephalosporins

The cephalosporins structurally related to the penicillins consist of a -lactam ring attached to a dihydrothiazoline ring. Substitutions of chemical groups result in varying pharmacologic properties and antimicrobial activities.

The mechanism of action of cephalosporins is analogous to that of the penicillins: (1) binding to specific penicillin-binding proteins, (2) inhibition of cell wall synthesis, and (3) activation of autolytic enzymes in the cell wall. Resistance to cephalosporins may be due to poor permeability of the drug into bacteria, lack of penicillin-binding proteins, or degradation by -lactamases.

Cephalosporins have been divided into four major groups or "generations" (Table 30–5) based on their antibacterial activity: First-generation cephalosporins have good activity against aerobic gram-positive organisms and some community-acquired gram-negative organisms (*P mirabilis, Escherichia coli, Klebsiella* species); second-generation drugs have a slightly extended spectrum against gram-negative bacteria, and some are active against gram-negative anaerobes; and third-generation cephalosporins are active against many gram-negative bacteria. Not all cephalosporins fit neatly into this grouping, and there are exceptions to the general characterization of the drugs in the individual classes; however, the generational classification of cephalosporins is useful for discussion purposes. Cefepime is considered a fourth-generation agent because it is more stable against plasmid-mediated -lactamase and has little or no -lactamase-inducing capacity. Cefepime compares favorably with ceftazidime with respect to its gram-negative activity; however, its stability versus plasmid-mediated -lactamase results in improved coverage against *Enterobacter* and *Citrobacter* species. The gram-positive coverage of cefepime approaches that of cefotaxime or ceftriaxone. None of the currently available agents are active against the enterococcus. While yet to be approved, a fifth-generation cephalosporin, ceftobiprole, is uniquely active against methicillin-resistant *Staphylococcus aureus* and *E faecalis*. Ceftobiprole additionally has a gram-negative spectrum of activity similar to cefepime.

First-Generation Cephalosporins

Antimicrobial Activity

In vitro activity includes coverage of gram-positive cocci, including penicillin-susceptible pneumococci, viridans streptococci, group A hemolytic streptococci, and *S aureus*. As with all first-, second-, third-, and fourth-generation cephalosporins, they are inactive against enterococci and methicillin-resistant staphylococci. Activity against *H influenzae* is poor, and penicillin-resistant streptococci (both intermediately and highly resistant) are resistant to first-generation cephalosporins. Among gram-negative bacteria, *E coli*, *Klebsiella pneumoniae*, and *P mirabilis* are the most likely susceptible. Anaerobic gram-positive cocci are usually susceptible, but *B fragilis* is not.

Pharmacokinetics & Administration

Oral

Cephalexin, cephradine, and cefadroxil are generally well absorbed. Cefadroxil, because of its longer half-life, can be given twice daily instead of four times daily.

Intravenous

Cefazolin is preferred because its longer half-life allows for less frequent dosing. In kidney disease, it requires dosage adjustment.

Intramuscular

Cefazolin can be given intramuscularly; however, the intravenous route is preferred because of the every 8-hour dosing schedule.

Clinical Uses

Oral drugs are used for treatment of urinary tract infections, and they can be used for minor skin and soft tissue infections (eg, cellulitis, soft tissue abscess). However, the increase in the incidence of community-associated *S aureus* has diminished the utility of these agents in these infections.

Intravenous first-generation cephalosporins are the drugs of choice for most clean surgical prophylaxis; however, institutions with high rates of postoperative surgical site infection with methicillin-resistant isolates should consider the use of other agents, such as vancomycin. The second-generation cephalosporins cefoxitin and cefotetan have expanded anaerobic activity and are superior to first-generation agents as prophylaxis for colorectal surgery or for hysterectomy.

First-generation cephalosporins do not adequately penetrate into cerebrospinal fluid and are less potent than second- and third-generation agents and cannot be used to treat meningitis.

Second-Generation Cephalosporins

Second-generation cephalosporins are a heterogeneous group with marked individual differences in activity, pharmacokinetics, and toxicity. In general, they are active against gram-negative organisms inhibited by first-generation drugs, but they have an extended gram-negative coverage. Indole-positive *Proteus* and *Klebsiella* (including first-generation cephalosporin-resistant strains) as well as *M catarrhalis* and *Neisseria* species are usually sensitive. Cefuroxime is active against *H influenzae*, including -lactamase-producing strains, but has little activity against *Serratia* and *B fragilis.* In contrast, cefoxitin and cefotetan are active against many strains of *B fragilis* and some strains of *Serratia.* Against gram-positive organisms, second-generation agents are generally less active than the first-generation cephalosporins (cefuroxime is an exception). Second-generation agents have no activity against *P aeruginosa*.

Pharmacokinetics & Administration

Oral

Only cefaclor, cefuroxime axetil, and cefprozil can be given orally. Cefuroxime axetil is deesterified to cefuroxime after absorption. Its longer half-life permits twice-daily dosing, and absorption is enhanced when it is taken with food (as is not the case with many other oral antibiotics).

Intravenous and Intramuscular

Because of differences in drug half-life and protein binding, peak serum levels achieved and dosing intervals vary greatly for this group of drugs (Table 30–6). Drugs with shorter half-lives (cefoxitin) require more frequent dosing than drugs with longer half-lives (eg, cefuroxime). Dosage adjustment is required with kidney disease.

Clinical Uses

Because of their activity against -lactamase–producing *H influenzae* and *M catarrhalis*, cefprozil and cefuroxime axetil have a role in the treatment of sinusitis and otitis media in those patients unresponsive to more established agents.

Because of their activity against *B fragilis*, cefoxitin and cefotetan can be used to treat mixed anaerobic infections, eg, peritonitis and diverticulitis. However, since many *B fragilis* and enteric gram-negative organisms are resistant, alternative agents are preferred for life-threatening intra-abdominal infections. Cefoxitin and cefotetan are useful as prophylaxis in colorectal surgery, vaginal or abdominal hysterectomy, and appendectomy due to its moderate to strong activity against *B fragilis*.

Third- & Fourth-Generation Cephalosporins

Antimicrobial Activity

Most of these drugs are active against staphylococci (not methicillin-resistant strains) but less so than first-generation cephalosporins. Ceftazidime, however, has notably weak activity against *S aureus* and pneumococci. While inactive against enterococci, most third- and fourth-generation cephalosporins inhibit most streptococci (ceftazidime is an exception to this rule). Ceftriaxone and cefotaxime offer the most reliable antipneumococcal coverage. A major advantage of these cephalosporins is their expanded gram-negative coverage. In addition to organisms inhibited by other cephalosporins, they are consistently active against *Serratia marcescens*, *Providencia*, *Haemophilus*, and *Neisseria*, including -lactamase–producing strains. Ceftazidime is unique among all third-generation agents because it is active against *P aeruginosa*. *Acinetobacter*, *Citrobacter*, *Enterobacter*, and nonaeruginosa strains of *Pseudomonas* are variably sensitive to third-generation cephalosporins, and Listeria is uniformly resistant. Activity against *B fragilis* is variable. In contrast to the third-generation agents, cefepime—the only currently available fourth-generation cephalosporin—is more active against *Enterobacter* and *Citrobacter*, has activity comparable to that of ceftazidime against *P aeruginosa*, and has gram-positive activity similar to that of ceftriaxone.

Cefpodoxime proxetil, cefdinir, cefditoren pivoxil, cefixime, and ceftibuten (the only oral agents in this group) are more active than cefuroxime axetil against gram-negative pathogens. However, none of these agents are equal to the parenteral third-generation cephalosporins against these pathogens. All third- and fourth-generation cephalosporins are active against *Streptococcus pyogenes* (group A *Streptococcus*). Cefpodoxime proxetil, cefditoren pivoxil, and cefdinir are active against methicillin-sensitive *S aureus*, whereas ceftibuten has little activity (none are active against methicillin-resistant strains). Cefdinir, cefditoren pivoxil, and cefpodoxime proxetil are active against penicillin-sensitive strains of *Streptococcus pneumoniae* (the pneumococcus), but ceftibuten has marginal activity. None of the oral cephalosporins are reliable against intermediately susceptible or penicillin-resistant *S pneumoniae*. Like other members of this class, these drugs are ineffective against enterococci and *Listeria monocytogenes*.

Pharmacokinetics & Administration

The intravenous agents distribute into extracellular fluid and reach levels in the cerebrospinal fluid exceeding those needed to inhibit susceptible pathogens. The half-lives of these drugs are variable, resulting in differing dosage needs (Table 30–6). Ceftriaxone is eliminated primarily by biliary excretion, and no dosage adjustment is required in kidney disease. The other drugs are eliminated primarily by the kidney and thus require dosage adjustment in kidney disease.

Clinical Uses

Because of their penetration into the cerebrospinal fluid and potent in vitro activity, intravenous third-generation cephalosporins are useful to treat meningitis due to susceptible pneumococci, meningococci, *H influenzae*, and susceptible enteric gram-negative rods. In meningitis in older patients, third-generation cephalosporins should be combined with ampicillin or trimethoprim-sulfamethoxazole until *L monocytogenes* has been excluded as the etiologic pathogen. Ceftazidime has been used to treat meningitis due to

Pseudomonas. The dosage for meningitis should be at the upper limits of the recommended range, because cerebrospinal fluid levels of these drugs are only 10–20% of serum levels. Ceftazidime or cefepime is frequently administered empirically in the febrile neutropenic patient. Ceftriaxone is indicated for gonorrhea, chancroid, and more serious forms of Lyme disease. Because of its long half-life and once-daily dosing requirement, ceftriaxone is an attractive option for the outpatient parenteral therapy of infections due to susceptible organisms.

Cefepime is useful for third-generation cephalosporin–resistant isolates such as *Enterobacter* and *Citrobacter*. While cefepime has an extended spectrum of activity compared with third-generation agents, a meta-analysis revealed increased all-cause mortality with this agent when compared with other -lactams. While a clear mechanism for this observation has not been determined, neurotoxicity and inadequate pharmacodynamics have been suggested.

Cefdinir, cefditoren pivoxil, and cefpodoxime proxetil are the best third-generation oral agents against pneumococci and *S aureus*. While cefixime had only been available in an oral suspension, the 400-mg tablets have been available in the United States since 2008. This latter dosage form is important because it is the only oral agent recommended by the Centers for Disease Control and Prevention (CDC) for the treatment of uncomplicated urogenital or rectal gonorrhea.

Adverse Effects of Cephalosporins

Allergy

Cephalosporins are sensitizing, and a variety of hypersensitivity reactions occur, including anaphylaxis, fever, skin rashes, nephritis, and hemolytic anemia. The frequency of IgE cross-allergy between cephalosporins and penicillins approximates 5–10%. Persons with a history of anaphylaxis to penicillins should not receive cephalosporins. Allergies to a given agent may or may not extend to the entire cepaphalosporin class.

Toxicity

Ceftriaxone has been associated with a dose-dependent biliary sludging syndrome and cholelithiasis due to precipitation of drug when its solubility in bile is exceeded. Long-term administration of 2 g/d or more is a risk factor for this complication. Cefepime may be associated with an increased rate of neurotoxicity, particularly with large doses and concomitant kidney disease.

Noel GJ et al. A randomized, double-blind trial comparing ceftobiprole medocaril with vancomycin plus ceftazidime for the treatment of patients with complicated skin and skin-structure infections. Clin Infect Dis. 2008 Mar 1;46(5):647–55. [PMID: 18225981]

Romano A et al. Cross-reactivity and tolerability of cephalosporins in patients with immediate hypersensitivity to penicillins. Ann Intern Med. 2004 Jul 6;141(1):16–22. [PMID: 15238366]

Yahav D et al. Efficacy and safety of cefepime: a systemic review and meta-analysis. Lancet Infect Dis. 2007 May;7(5):338–48. [PMID: 17448937]

Monobactams

Aztreonam is the sole marketed monobactam, so named due its monocyclic -lactam ring resistant to many -lactamases. Aztreonam is active against gram-negative organisms (including *Pseudomonas*) but has no activity against gram-positive organisms or anaerobes. Aztreonam resembles ceftazidime in its gram-negative activity. Clinical uses of aztreonam are limited because of the availability of third-generation cephalosporins with a broader spectrum of activity and minimal toxicity. Despite the structural similarity of aztreonam to penicillin, cross-reactivity is limited, and it can therefore be used in most patients with IgE-mediated penicillin allergy.

Carbapenems

This class of drugs is structurally related to -lactam antibiotics. Imipenem, the first drug of this type, has a wide spectrum of activity that includes most gram-negative rods (including *P aeruginosa*) and gram-positive organisms and anaerobes, with the exception of *Burkholderia cepacia*, *Stenotrophomonas maltophilia*, *Enterococcus faecium*, and methicillin-resistant *S aureus* and *Staphylococcus epidermidis*. The half-life of imipenem is 1 hour. Dosage adjustment is required in kidney disease.

Meropenem and doripenem are similar to imipenem in spectrum of activity and pharmacology. Both are less likely to cause seizures than imipenem, although the risk of seizures is low with imipenem if dosage is appropriately adjusted for kidney disease. Meropenem and doripenem are associated with less nausea and vomiting than imipenem, a feature of importance when high doses must be used, as in the treatment of *Pseudomonas* infection in patients with cystic fibrosis. The usual dose for meropenem is 1–2 g intravenously every 8 hours. Dosage adjustment in kidney disease is required. Doripenem (500 mg-1 g intravenously every 8 hours) is used in the treatment of intra-abdominal infection and pyelonephritis. Unlike meropenem, doripenem is not approved for the treatment of other serious hospital-acquired infections.

Ertapenem is similar to the other carbapenems in its activity against aerobic gram-positive and anaerobic organisms but is less active against *Pseudomonas* and *Acinetobacter*. Because of its long half-life (4 hours), it can be administered once daily. The usual dose is 1 g intravenously every 24 hours and adjustments are needed for kidney disease.

The carbapenems should not be routinely used as first-line therapy unless the pathogen is multidrug-resistant and is known to be susceptible to these agents. In patients hospitalized for a prolonged period with presumed infection with a multidrug-resistant organism, empiric use of carbapenems is reasonable. (Ertapenem should not be used if *Pseudomonas* and *Acinetobacter* are expected.) *Pseudomonas* may rapidly develop resistance to carbapenems. The use of imipenem or meropenem alone appears to be as effective as combination therapy in the febrile neutropenic patient, and the carbapenems are as effective as combination therapy in certain polymicrobial infections such as peritonitis and pelvic infections.

The most common adverse effects of carbapenems are diarrhea, reactions at the infusion site, and skin rashes. Seizures, nausea, and vomiting are more commonly observed with imipenem. Patients allergic to penicillins may be allergic to imipenem and meropenem as well. While earlier studies suggested up to 50% cross-reactivity between penicillin and imipenem in patients with confirmed IgE-mediated reactions to penicillin, more recent data strongly suggest the cross-reactivity is far less.

Erythromycin Group (Macrolides)

The macrolides are a group of closely related compounds characterized by a macrocyclic lactone ring to which various sugars are attached.

Antimicrobial Activity

Erythromycins inhibit protein synthesis by binding to the 50S subunit of bacterial ribosomes. They generally are bacteriostatic and sometimes bactericidal for gram-positive organisms, including most streptococci and corynebacteria. Similar to penicillin, the rate of macrolide-resistant *S pneumoniae* has increased (15–50%), and recent reports demonstrate increased resistance in group A streptococci in some centers. Erythromycin-resistant pneumococci are resistant to azithromycin and clarithromycin as well. *Chlamydia*, *Mycoplasma*, *Legionella*, and *Campylobacter* organisms are susceptible.

Pharmacokinetics & Administration

Preparations for oral use include erythromycin base, erythromycin stearate, estolate, and ethyl succinate.

Erythromycins are excreted primarily nonrenally; no adjustment is therefore required in kidney disease.

Azithromycin is available for intravenous use, particularly in the treatment of Legionnaire disease.

Clinical Uses

Macrolides are effective in the treatment of infection due to *Legionella*, *Mycoplasma*, *Ureaplasma*, *Corynebacterium* (including diphtheria), and *Chlamydia* (including ocular and respiratory infections) organisms. They are useful adjuncts in the treatment of streptococcal and pneumococcal disease in penicillin-allergic patients. Oral erythromycin base is used with neomycin as prophylaxis for colonic surgery. When administered early, erythromycin may shorten the course of *Campylobacter* enteritis. Erythromycins are effective against certain *Bartonella* species (bacillary angiomatosis) and *Rhodococcus* species. In vitro data suggest that macrolides have a direct effect on neutrophil function and the production of cytokines associated with inflammation. Thus, these agents are being evaluated for their anti-inflammatory effects as well. The most well-documented anti-inflammatory benefit associated with the macrolides (azithromycin) is in the prevention of cystic fibrosis exacerbation. A potential link between chlamydial infection and coronary disease was identified, and it was hypothesized that the benefit of macrolides was due to the antichlamydial activity of these agents. However, large subsequent trials have refuted this benefit.

Adverse Effects

Nausea, vomiting, and diarrhea may occur after oral or intravenous intake. Erythromycins—particularly the estolate—can produce acute cholestatic hepatitis (fever, jaundice, impaired liver function), probably as a hypersensitivity reaction. Hepatitis recurs if the drug is readministered. Reversible auditory impairment occurs with large erythromycin doses (4 g/d or more), particularly in patients with impaired kidney or liver function. However, ototoxicity has been reported with high doses of all agents. Intravenous erythromycin has been associated with prolongation of the QT interval and torsades de pointes—more commonly in women. Erythromycins (and clarithromycin) can increase the effects of oral anticoagulants, digoxin, theophylline, and cyclosporine by inhibiting cytochrome P450. An increased risk of cardiac-associated death has been reported with erythromycin, particularly in patients receiving concomitant inhibitors of cytochrome P450 3A4.

Azalides

Azalides (azithromycin, clarithromycin, and others) are closely related structurally to the macrolides. They are similar to erythromycin in activity against most organisms and are slightly more active in vitro than erythromycin against *H influenzae* (azithromycin > clarithromycin > erythromycin). They are also active against *Chlamydia trachomatis*, *Ureaplasma urealyticum*, and *Haemophilus ducreyi.* In addition, these drugs have in vitro activity against a number of unusual pathogens, including atypical mycobacteria *(Mycobacterium avium-intracellulare*, *Mycobacterium chelonei*, *Mycobacterium fortuitum*, *Mycobacterium marinum), Toxoplasma gondii*, *Campylobacter jejuni*, *Helicobacter pylori*, and *Borrelia burgdorferi.*

Azithromycin and clarithromycin are more acid-stable than erythromycin, concentrate intracellularly and in tissues, and have a long terminal half-life, with high tissue concentrations that persist for days. The elevated tissue levels associated with azithromycin and clarithromycin has been proposed to overcome the high incidence of in vitro resistance seen with pneumococci (30%), but clinical observations have confirmed that in vitro resistance is associated with clinical failure. Azithromycin and clarithromycin are approved for treatment of streptococcal pharyngitis, uncomplicated skin infections, and acute bacterial exacerbations of chronic bronchitis. Because of the long half-life, outpatient oral treatment with azithromycin is with once-daily dosing for a total of 5 days (500 mg on day 1 and then 250 mg on days 2–5). Clarithromycin is usually administered in a dosage of 250–500 mg orally twice daily, although an extended-release formulation that is given as a single daily 1000-mg dose is approved for acute sinusitis and acute exacerbation of chronic bronchitis. The azalides are more expensive than erythromycin; however, the less frequent dosing and better tolerability make them preferable choices in most patients.

Azithromycin has also been approved as single-dose therapy (1 g) for chlamydial genital infections. While more expensive than 7 days of treatment with doxycycline (Table e1–1), the assurance of adequate supervised therapy makes azithromycin preferred therapy in most patients. Azithromycin can also be used as single-dose therapy (1 g) for chancroid, and a single dose of 1 g is as efficacious as 7 days of doxycycline for nongonococcal urethritis in men and incubating syphilis. While a 2-g dose of azithromycin is used for the treatment of gonorrhea, its efficacy is less than that observed with ceftriaxone. Furthermore, upper gastrointestinal intolerance is common with this dose. A single dose of azithromycin (20 mg/kg, maximum dose of 1 g) is effective in treating trachoma and substantially reduces disease burden in endemic areas. A 1-g dose of azithromycin is also effective therapy for severe cholera. The spectrum of activity of the macrolides—particularly their atypical coverage—results in their usefulness in mild to moderate cases of community-acquired pneumonia; however, penicillin-resistant strains are often resistant to these agents as well. Weekly 1200-mg doses of azithromycin are effective in preventing *Mycobacterium avium* complex infections in HIV-positive patients, and doses of 500 mg daily are useful in *M avium* complex pulmonary infections in non–HIV-positive patients. Azithromycin is effective in the treatment of dysentery caused by multidrug-resistant *Shigella* and *Campylobacter* organisms. Used as prophylaxis, azithromycin (500 mg weekly) is as effective as benzathine penicillin in preventing upper respiratory tract infections in military recruits, and at a dose of 250 mg daily it is adequate as prophylaxis for malaria (although inferior to doxycycline for multidrug-resistant *Plasmodium falciparum*). Clarithromycin has been used for the therapy of *M avium* complex infections, usually in combination with other drugs (eg, rifabutin and ethambutol), and can be given daily (500 mg twice daily) or three times weekly (1000 mg) as intermittent therapy. Oral clarithromycin (500 mg twice daily for 6 months), in combination with other agents, is effective therapy for disseminated *M chelonei* infections. Clarithromycin has also been used in combination regimens for the therapy of *H pylori* infections. When clarithromycin is given with omeprazole and amoxicillin, cure rates in excess of 80–90% have been achieved. The broad use of the macrolides has resulted in increased bacterial resistance. A prospective, randomized trial of healthy volunteers treated with azithromycin or clarithromycin revealed rapid increases in macrolide-resistant streptococci, which continue up to 6 months after the course of therapy. Furthermore, clarithromycin, but not azithromycin, was found to also increase the proportion of the more resistant MLS phenotype resistance.

Table e1–1. Approximate costs of antimicrobials.

Drug	**Dose per Day**[1]	**Cost per Unit**[2]	**Daily Cost of Therapy**[3]
INTRAVENOUS PREPARATIONS			
Acyclovir	15 mg/kg (mucocutaneous	$19.20/1 g	$19.20

	herpes)		
Acyclovir	30 mg/kg (CNS herpes)	$19.20/1 g	$38.40
Amikacin (Amikin, others)	15 mg/kg	$6.00/0.5 g	$12.00
Ampicillin	100 mg/kg	$16.75/2 g	$67.00
Ampicillin plus sulbactam (Unasyn)	3 g q8h	$11.00/3 g (IV)	$33.00
Aztreonam (Azactam)	50 mg/kg	$34.96/1 g	$139.84
Anidulafungin (Eraxis)	100 mg	$216.00/100 mg	$216.00
Caspofungin (Cancidas)	50 mg	$405.25	$405.25
Cefazolin (Ancef, others)	50 mg/kg	$1.75/1 g (IV)	$5.25
Cefepime (Maxipime)	500 mg/kg	$20.33/1 g	$60.99
Cefoxitin (Mefoxin)	80 mg/kg	$10.80/1 g	$32.40

Ceftazidime (Fortaz, others)	50 mg/kg	$12.60/1 g	$37.80
Ceftriaxone (Rocephin)	30 mg/kg	$6.62/1 g	$6.62
Cefuroxime (Zinacef, others)	60 mg/kg	$13.46/1.5 g	$40.38
Ciprofloxacin (Cipro IV)	0.8 mg	$28.80/0.4 g	$57.60
Clindamycin (Cleocin, others)	2400 mg	$4.10/0.6 g	$16.40
Daptomycin (Cubicin)	4 mg/kg	$222.80/500 mg	$222.80
Fluconazole (Diflucan IV)	0.2–0.4 g	$21.00/0.2 g $40.83/0.4 g	$21.00–40.83
Foscarnet (Foscavir)	180 mg/kg (induction)	$79.00 (24 mg/mL x 250 mL = 6000 mg)	$158.00
	90–120 mg/kg (maintenance)		$79.00–105.00
Ganciclovir	10 mg/kg	$64.14/0.5	$128.28

(Cytovene IV)		g	
Gentamicin	5 mg/kg	$0.86/80 mg	$2.58
Imipenem (Primaxin IV)	50 mg/kg	$41.26/0.5 g	$165.04
Meropenem (Merrem IV)	50 mg/kg	$36.85/0.5 g	$110.55–147.40
Metronidazole (Flagyl, others)	1500 mg	$3.00/0.5 g	$9.00
Micafungin (Mycamine)	100 mg	$112.20/50 mg	$224.40
Nafcillin	100 mg/kg	$16.75/2 g	$67.00
Penicillin	12 million units	$12.67/1 million units	$152.00
Piperacillin plus tazobactam (Zosyn)	3.75 g q6–8h	$19.69/3.375 g	$78.76
Tigecycline (Tygacil)	50 mg q12h	$60.67/50 mg	$121.34
Tobramycin	5 mg/kg	$2.35/80 mg	$9.40

Trimethoprim-sulfamethoxazole (Bactrim, Septra)	15 mg/kg TMP	$16.08 (0.48 g TMP in 30 mL)	$32.16
Vancomycin	20–30 mg/kg	$8.71/1 g	$17.42
Voriconazole (VFend)	200 mg q12h	$121.63/200 mg	$243.26
ORAL PREPARATIONS			
Acyclovir	1000 mg (therapy of herpes)	$0.97/0.2 g	$4.85
Acyclovir	800 mg three times daily (herpes suppression for immunocompromised patient)	$4.20/0.8 g	$12.60
Amoxicillin	20–30 mg/kg	$0.43/0.5 g	$1.29
Ampicillin	20–30 mg/kg	$0.40/0.5 g	$1.60
Augmentin (0.5 g amoxicillin plus 0.125 g clavulanic	30 mg/kg	$3.80/0.5 g	$7.60

acid)			
Azithromycin (Zithromax)	500 mg as loading dose, then 250 mg/d for 4 days	$7.80/0.25 g	$15.60 load, then $7.80
Azithromycin (Zithromax)	1 g as single dose for *C trachomatis* infection	$24.15/1 g packet	$24.15/ 1 g packet
Cefaclor (Ceclor)	20–30 mg/kg	$3.90/0.5 g	$11.70
Cefditoren (Spectracef)	400 mg twice daily	$3.12/200 mg	$12.48
Cefpodoxime proxetil (Vantin)	400 mg	$6.75/0.2 g	$13.50
Cefprozil (0.5 g) (Cefzil)	15 mg/kg	$8.90/0.5 g	$17.80
Cefuroxime (0.5 g) (Ceftin)	0.5 g twice daily	$8.00/0.5 g	$16.00
Cephalexin (0.5 g) (Keflex, others)	30 mg/kg	$1.40/0.5 g	$5.60
Ciprofloxacin	0.5–0.75 g twice	$5.40/0.5	$10.80

(0.5 g) (Cipro)	daily	g	
Ciprofloxacin (0.75 g) (Cipro)		$5.63/0.75 g	$11.26
Clarithromycin (0.25 or 0.5 g) (Biaxin)	250–500 mg twice daily	$4.52/0.5 g	$9.04
Clindamycin (0.3 g) (Cleocin, others)	15 mg/kg	$1.20/150 mg	$9.60
Doxycycline (0.1 g)	3 mg/kg	$1.35/0.1 g	$2.70
Erythromycin (0.5 g)	30 mg/kg	$0.29/0.5 g	$0.87
Famciclovir (0.5 g) (Famvir)	500 mg three times daily	$12.84/0.5 g	$38.50
Fluconazole (0.1 g)	0.1–0.2 g daily	$8.75/0.1 g	$8.75
Fluconazole (0.2 g) (Diflucan)		$14.32/0.2 g	$14.32
Flucytosine (0.5 g)	150 mg/kg	$12.39/0.5 g	$247.80

(Ancobon)			
Gemifloxacin (.32 g) (Factiv)	320 mg	$27.12/320 mg	$27.12
Itraconazole (0.1 g) (Sporanox)	200–400 mg	$9.28/0.1 g	$18.56–37.12
Levofloxacin (0.5 g) (Levaquin)	0.5 g daily	$14.70/0.5 g	$14.70
Loracarbef (0.4 mg) (Lorabid)	800 mg	$4.70/0.2 g	$18.80
Metronidazole (0.5 g) (Flagyl)	20 mg/kg	$0.20/0.5 g	$0.60
Moxifloxacin (0.4 g) (Avelox)	400 mg	$15.10/0.4 g	$15.10
Ofloxacin (0.4 g) (Floxin)	400 mg twice daily	$6.00/0.4 g	$12.00
Penicillin VK (0.5 g)	30 mg/kg	$0.38/0.5 g	$1.52
Telithromycin (Ketec)	800 mg	$5.76/400 mg	$11.52

Tetracycline (0.5 g)	30 mg/kg	$0.12/0.5 g	$0.48
Trimethoprim-sulfamethoxazole (Bactrim, Septra)	5 mg/kg TMP	$1.08/160 mg TMP and 800 mg SMZ	$2.16
Valacyclovir (0.5 g) (Valtrex)	0.5–1 g three times daily	$7.15/0.5 g	$21.45–42.90
Valganciclovir 450 mg (Valcyte)	0.9 g twice daily	$38.44/450 mg	$153.76
Vancomycin (Vancocin)	125 mg three times daily	$19.34/125 mg	$58.02
Voriconazole (VFend)	200 mg twice daily	$41.33/200 mg	$82.66

[1] Doses based on a 70-kg individual with normal kidney function.

variations exist among institutions.

[3] Daily cost for intravenous antibiotics includes acquisition cost only and not preparation and administration costs.

Adverse effects of azithromycin and clarithromycin are similar to those of erythromycin, but upper gastrointestinal upset, the major side effect, occurs less often with the azalides. Hepatic enzyme elevations and reversible cochlear toxicity have been reported. Clarithromycin is similar to erythromycin in its effect on the cytochrome P450 system. Azithromycin is associated with minimal to no drug interactions.

Malhotra-Kumar S et al. Effect of azithromycin and clarithromycin therapy on pharyngeal carriage of macrolide-resistant streptococci in healthy volunteers: a randomised, double-blind, placebo-controlled study. Lancet. 2007 Feb 10;369(9560):482–90. [PMID: 17292768]

Robenshtok E et al. Empiric antibiotic coverage of atypical pathogens for community acquired pneumonia in hospitalized adults. Cochrane Database Syst Rev. 2008 Jan 23;(1):CD004418. [PMID: 18254049]

Ketolides

Telithromycin, the one available ketolide, is similar in structure to macrolides but has a broader spectrum of activity. Telithromycin offers activity against both penicillin-resistant and macrolide-resistant pneumococci and is equal to azithromycin against atypical pathogens and *H influenzae.* The dose is 800 mg/d orally, and no adjustment is needed for kidney disease or liver insufficiency. Upon telithromycin's approval, upper gastrointestinal toxicity and visual disturbances (occurring more frequently in women than men) were the most commonly observed adverse events. However, telithromycin has more recently been associated with severe hepatotoxicity resulting in liver transplant and death. Telithromycin also has been found to exacerbate myasthenia gravis. Cytochrome P450 inhibition with telithromycin approximates that of erythromycin, and increased serum levels of warfarin and other agents would be expected with concomitant administration of telithromycin. The serious hepatotoxicity of telithromycin significantly limits its use in the treatment of outpatient respiratory tract infection. There is no clear indication for this agent.

Tetracycline Group

The tetracyclines are a group of drugs with common basic chemical structures, antimicrobial activity, and pharmacologic properties.

Antimicrobial Activity

Tetracyclines are inhibitors of protein synthesis and are bacteriostatic for many gram-positive and gram-negative bacteria. They are strongly inhibitory for the growth of mycoplasmas, rickettsiae, chlamydiae, spirochetes, and some protozoa (eg, amebas). Their antipneumococcal activity approaches that of the macrolides; almost all *H influenzae* are inhibited. Tetracyclines also have some activity against some vancomycin-resistant enterococci. Doxycycline and minocycline are potential options for therapy of staphylococcal infections, including infections with many methicillin-resistant strains. There are marked in vitro differences between tetracyclines with respect to staphylococci. Tetracycline-resistant staphylococci often retain susceptibility to doxycycline and minocycline. Tetracyclines have little utility in the treatment of gram-negative aerobic infection. However, minocycline is reliable in its activity against *S maltophilia*.

Pharmacokinetics & Administration

Oral bioavailability varies depending on the drug. Absorption is impaired by dairy products, aluminum hydroxide gels (antacids), and chelation with divalent cations, eg, Ca^{2+} or Fe^{2+}. Chelation is less problematic with doxycycline and minocycline when compared with tetracycline. Consequently, doses of tetracyclines should be staggered at least 2 hours before or after receipt of multivalent cations. Oral bioavailability is moderate with tetracycline and highest with doxycycline and minocycline (95% or more). Lipid solubility of minocycline and doxycycline accounts for their penetration into the cerebrospinal fluid, prostate, tears, and saliva.

Tetracyclines are primarily metabolized in the liver and excreted in bile. Doxycycline requires no dosage adjustment in kidney disease; in contrast, other tetracyclines should be avoided or given in reduced dosage.

For patients unable to take oral medication, some tetracyclines (doxycycline, minocycline) are formulated for parenteral administration in doses similar to the oral ones.

Clinical Uses

Tetracyclines are drugs of choice for infections with *Chlamydia, Mycoplasma, Rickettsia, Ehrlichia,* and *Vibrio* organisms and for some spirochetal infections. Sexually transmitted diseases in which chlamydiae often play a role—endocervicitis, urethritis, proctitis, and epididymitis—should be treated with doxycycline for 7–14 days. Pelvic inflammatory disease is often treated with doxycycline plus cefoxitin or cefotetan. Other chlamydial infections (psittacosis, lymphogranuloma venereum, trachoma) and sexually transmitted diseases (granuloma inguinale) also respond to doxycycline. Other uses include treatment of acne, respiratory infections, Lyme disease and relapsing fever, brucellosis, glanders, tularemia (often in combination with streptomycin), cholera, mycoplasmal pneumonia, actinomycosis, nocardiosis, malaria, infections caused by *M marinum* and *Pasteurella* species (typically after an animal bite), and as malaria prophylaxis (including multidrug-resistant *P falciparum*). They also have been used in combination with other drugs for amebiasis, falciparum malaria, and recurrent ulcers due to *H pylori.* Because of generally good activity against pneumococci; *H influenzae;* and *Chlamydia, Legionella,* and *Mycoplasma* organisms, doxycycline should be considered as a potential empiric therapy for mild to moderate outpatient pneumonia. Tetracyclines are increasingly considered as options in the treatment of community-onset skin and soft tissue infection due to methicillin-resistant *S aureus*. Minocycline and doxycycline are superior to tetracycline in the treatment of methicillin-resistant *S aureus*.

Minocycline is equally as efficacious as doxycycline for the therapy of nongonococcal urethritis and cervicitis.

Adverse Effects

Allergy

Hypersensitivity reactions with fever or skin rashes are uncommon.

Gastrointestinal Side Effects

Diarrhea, nausea, and anorexia are common. Tetracycline administration, particularly doxycycline and minocycline, should be avoided at bedtime due to the risk of esophageal erosion.

Bones and Teeth

Tetracyclines are bound to calcium deposited in growing bones and teeth, causing fluorescence, discoloration, enamel dysplasia, deformity, or growth inhibition. Therefore, tetracyclines should not be given to pregnant women, nursing women, or children under 8 years of age.

Liver Damage

Tetracyclines can impair hepatic function or even cause liver necrosis, particularly in the presence of preexisting liver disease.

Kidney Effects

Demeclocycline can cause nephrogenic diabetes insipidus and has been used therapeutically to treat inappropriate antidiuretic hormone secretion. Tetracyclines, particularly tetracycline, may increase blood urea nitrogen (BUN) due to their antianabolic activity.

Other

Tetracyclines—principally demeclocycline—may induce photosensitization, especially in fair-skinned individuals. Minocycline induces vestibular reactions (dizziness, vertigo, nausea, vomiting), with a frequency of 35–70% after doses of 200 mg daily and has also been implicated as a cause of hypersensitivity pneumonitis.

Glycylcyclines

Tigecycline, a tetracycline derivative, is available as a parenteral antibacterial for the treatment of nosocomial infection. It is active against most gram-positive bacteria, including methicillin-resistant staphylococci and vancomycin-resistant enterococci and many multidrug resistant aerobic gram-negative bacilli, including *Acinetobacter, Enterobacter,* and *Citrobacter.* However, tigecycline has little to no activity against *Pseudomonas* and only modest activity versus *Proteus* spp. In addition, tigecycline demonstrates excellent anaerobic activity against *B fragilis* and gram-positive anaerobes. A loading dose of 100 mg is administered intravenously with maintenance at 50 mg every 12 hours. The drug distributes into deep compartments with a large volume of distribution and low serum levels. Considering the low achievable serum levels associated with tigecycline, this agent should be used cautiously in bacteremic patients. The drug is primarily eliminated via biliary/fecal excretion with a half-life of 30–40 hours. Dose adjustment to 25 mg every 12 hours is recommended in Child-Turcotte-Pugh C liver disease. Tigecycline has similar adverse events as the tetracyclines; upper gastrointestinal side effects are particularly common. While approved for complicated skin and soft-tissue infection and intra-abdominal infection, tigecycline likely will have a role in the treatment of certain resistant gram-negative pathogens, including extended-spectrum -lactamase (ESBL)–producing organisms. However, at the present, considering the low associated serum levels, tigecycline should not be used in septic patients.

Ruhe JJ et al. Tetracyclines as an oral treatment option for patients with community onset skin and soft tissue infections caused by methicillin-resistant *Staphylococcus aureus*. Antimicrob Agents Chemother. 2007 Sep;51(9):3298–303. [PMID: 17576834]

Stein GE et al. Tigecycline: a critical analysis. Clin Infect Dis. 2006 Aug 15;43(4):518–24. [PMID: 16838243]

Chloramphenicol

Antimicrobial Activity

Chloramphenicol is active against certain rickettsiae. It binds to the 50S subunit of ribosomes and inhibits protein synthesis. While active against *S pneumoniae, H influenzae*, and *Neisseria meningitidis,* it is used minimally because of its toxicity and the availability of alternative agents.

Pharmacokinetics & Administration

Chloramphenicol is widely distributed in tissues, including the eye and cerebrospinal fluid. Chloramphenicol is metabolized in the liver, and less than 10% is excreted unchanged in the urine. Thus, no dosage adjustment is needed in kidney disease. Patients with liver disease may accumulate the drug, and levels should be monitored.

Clinical Uses

Chloramphenicol is an occasional alternative to more standard therapy for (1) meningococcal, *H influenzae*, or pneumococcal infections of the central nervous system; (2) anaerobic or mixed infections in the central nervous system, eg, brain abscess; (3) as an alternative to tetracyclines in rickettsial infections, especially in pregnant women, in whom tetracycline is contraindicated.

Adverse Effects

Chloramphenicol in excess of 50 mg/kg/d regularly causes reversible disturbances in red cell maturation within 1–2 weeks. In contrast, it is also associated with an irreversible aplastic anemia in 1:40,000–1:25,000 courses of chloramphenicol treatment.

Aminoglycosides

Aminoglycosides are a group of bactericidal drugs sharing chemical, antimicrobial, pharmacologic, and toxic characteristics. At present, the group includes streptomycin, neomycin, kanamycin, amikacin, gentamicin, tobramycin, sisomicin, netilmicin, paromomycin, and spectinomycin. All these agents inhibit protein synthesis in bacteria by inhibiting the function of the 30S subunit of the bacterial ribosome. Resistance is based on (1) a deficiency of the ribosomal receptor (chromosomal mutant); (2) the enzymatic destruction of the drug (plasmid-mediated transmissible resistance of clinical importance) by acetylation, phosphorylation, or adenylylation; or (3) a lack of permeability to the drug molecule or failure of active transport across cell membranes. Resistance can be chromosomal (eg, streptococci are relatively impermeable to aminoglycosides) or plasmid-mediated (eg, in gram-negative enteric bacteria). Anaerobic bacteria are resistant to aminoglycosides because transport across the cell membrane is an oxygen-dependent energy-requiring process.

All aminoglycosides are potentially ototoxic (cochlear and vestibular) and nephrotoxic, although to different degrees. All can accumulate in kidney disease; therefore, dosage adjustments must be made in patients with kidney dysfunction (see Table 30–7).

Because of their considerable toxicity and the availability of less toxic agents, (eg, cephalosporins, quinolones, carbapenems, -lactamase inhibitor combinations), aminoglycosides have been used less often in recent years. They are most commonly used to treat resistant gram-negative organisms that are sensitive only to aminoglycosides, or in low doses in combination with -lactam drugs or vancomycin for their synergistic effect (eg, enterococci, penicillin-resistant viridans streptococci, right-sided *S aureus* endocarditis, *S aureus* and *S epidermidis* prosthetic valve infection). Although aminoglycosides demonstrate in vitro activity against many gram-positive bacteria, they should never be used alone to treat infections caused by these organisms—both because there is minimal clinical experience with such infections and because less toxic alternatives are available. Aminoglycosides are inferior to -lactams as monotherapy in the treatment of *Pseudomonas* infections.

General Properties of Aminoglycosides

Because of the similarities of the aminoglycosides, a summary of properties is presented briefly.

Absorption, Distribution, Metabolism, and Excretion

Aminoglycosides are not absorbed from the gastrointestinal tract. They diffuse poorly into the eye, prostate, bile, central nervous system, and spinal fluid after parenteral injection.

The serum half-life is 2–3 hours in patients with normal kidney function. Excretion is almost entirely by glomerular filtration. Aminoglycosides are removed effectively by hemodialysis or continuous hemofiltration.

Dosage and Effect of Impaired Kidney Function

In persons with normal kidney function who have gram-negative infections, the dosage of amikacin is 15 mg/kg/d in a single daily dose; that for gentamicin, tobramycin, or netilmicin is 5 mg/kg injected once daily. A single large daily dose of gentamicin, tobramycin, netilmicin, or amikacin is as efficacious as—and no more nephrotoxic than—traditional dosing every 8–12 hours. When a single large daily dose is given, peak levels are not required. Trough aminoglycoside levels should be undetectable in patients with normal body composition and kidney function receiving once-daily dosing. Some clinicians recommend serum level monitoring 12–18 hours after the dose and extending the interval to every 48–72 hours for patients with elevated aminoglycoside levels. Others have suggested maintaining the dosage interval but decreasing the dose. Patients with kidney disease, volume overload, or obesity have altered antibiotic clearance or volume of distribution. In patients with abnormal kidney function or body composition, once-daily dosing is not recommended and aminoglycoside levels are recommended to guide dosing. For more traditional dosing, peak levels greater than 6 mcg/mL are desirable in the treatment of serious gram-negative infection, including pneumonia. Trough levels of more than 2 mcg/mL have been associated with an increased incidence of nephrotoxicity. In patients with normal body composition, once-daily dosing regimens as set forth in Table 30–7 should be followed. Reduced gentamicin doses (1 mg/kg every 8 hours) are recommended when used synergistically with -lactams or vancomycin in the treatment of serious gram-positive infection (eg, enterococcal endocarditis). While considered susceptible by Clinical and Laboratory Standards Institute (CLSI) standards, bacterial isolates with "susceptible" MICs of 1–4 mcg/mL treated with aminoglycosides lead to unacceptably low probability of good clinical outcome. Increasing the dose of aminoglycosides to improve chances for improved outcome is likely to be associated with an increased risk of ototoxicity and nephrotoxicity.

Adverse Effects

All aminoglycosides can cause ototoxicity and nephrotoxicity. Ototoxicity can be irreversible and is cumulative, presenting as hearing loss (cochlear damage), noted first with high-frequency tones, or as vestibular damage, manifested by vertigo and ataxia. Amikacin appears to be more cochlear-toxic than gentamicin, tobramycin, or netilmicin. Nephrotoxicity, which is more common than ototoxicity, is accompanied by rising serum creatinine levels or reduced creatinine clearance, or both. Nephrotoxicity is usually reversible and occurs with similar frequency with gentamicin, tobramycin, amikacin, and netilmicin.

In very high doses, usually associated with irrigation of an inflamed peritoneum, aminoglycosides can be neurotoxic, producing a curare-like effect with neuromuscular blockade that results in respiratory paralysis.

Streptomycin

The usual dosage of streptomycin is 15–25 mg/kg/d (about 1 g/d) injected in one or two divided doses intramuscularly. If administered over 30–60 minutes, it can also be given intravenously. Streptomycin exhibits all the adverse effects typically associated with the aminoglycosides; however, it has greater vestibular toxicity and probably less nephrotoxicity when compared with gentamicin.

Resistance emerges so rapidly and has become so widespread that only a few specific indications for this drug remain: plague and tularemia; endocarditis caused by *E faecalis* or viridans streptococci (use in conjunction with penicillin or vancomycin) in strains that are susceptible to high levels of streptomycin (ie, 2000 mcg/mL)—gentamicin may be substituted for streptomycin in this setting; active tuberculosis when other less toxic drugs cannot be used; and acute brucellosis (in combination with tetracycline).

Neomycin, Kanamycin, & Paromomycin

These aminoglycosides are closely related, with similar activity and complete cross-resistance. Systemic use has been abandoned because of ototoxicity and nephrotoxicity.

Neomycin, often combined with bacitracin and polymyxin, is a component of several over-the-counter topical ointments and creams. While the drug mixture covers most likely encountered staphylococci, streptococci, and gram-negative bacteria, the efficacy of topical application is questionable.

In preparation for elective bowel surgery, an option is 1 g of neomycin given orally every 6–8 hours for the day before surgery (combined with erythromycin, 1 g) to reduce bowel flora. Neomycin or kanamycin can give rise to allergic reactions when applied topically to skin or eye.

Paromomycin, closely related to neomycin and kanamycin, is poorly absorbed after oral administration and has been used mainly to treat asymptomatic intestinal amebiasis and in doses of 25–30 mg/kg/d in three divided doses for 7 days to treat giardiasis in pregnancy. A dosage of 500 mg orally three or four times daily is marginally effective for cryptosporidiosis in HIV/AIDS.

Amikacin

Amikacin is a semisynthetic derivative of kanamycin. It is relatively resistant to enzymes that inactivate gentamicin and tobramycin. Many gram-negative enteric bacteria—including many gentamicin-resistant strains of *Proteus*, *Enterobacter*, and *Serratia* organisms are inhibited. After injection of 500 mg of amikacin every 12 hours (15 mg/kg/d), peak levels in serum are 10–30 mcg/mL. In addition to therapy for serious gram-negative infections, amikacin is sometimes included with other drugs for therapy of *M avium* complex and *M fortuitum* complex.

Like all aminoglycosides, amikacin is nephrotoxic and ototoxic (particularly for the auditory portion of the eighth nerve). Drug levels should be monitored in patients with kidney disease.

Gentamicin

With doses of 5 mg/kg/d of this aminoglycoside, serum levels are sufficient for bactericidal effect against most gram-negative organisms. Enterococci generally are resistant; however, the addition of gentamicin to cell wall active agents, such as penicillin or vancomycin, is associated with increased bactericidal activity against this pathogen.

Indications, Dosages, & Routes of Administration

Gentamicin is used in serious infections caused by gram-negative bacteria. The usual dosage is 5 mg/kg/d intravenously administered once daily. In endocarditis due to viridans streptococci or *E faecalis*, gentamicin in lower synergistic doses (3 mg/kg/d) is combined with penicillin or ampicillin. A single daily dose of 3 mg/kg is just as effective as divided daily doses in the synergistic treatment of endocarditis due to viridans streptococci. In kidney disease, the dose should be adjusted as noted above.

Tobramycin

Tobramycin closely resembles gentamicin in antibacterial activity, toxicity, and pharmacologic properties and exhibits partial cross-resistance. It is more active than gentamicin against *P aeruginosa* but much less active than gentamicin when used synergistically with penicillin for enterococcal endocarditis. Dosing is the same as for gentamicin. Tobramycin is also given by aerosol (300 mg twice daily) to patients with cystic fibrosis and improves pulmonary function and decreases colonization with *Pseudomonas* without toxicity and with minimal selection for resistant strains.

Netilmicin shares many characteristics with gentamicin and tobramycin and can be given in a similar dosage. It may be less ototoxic and less nephrotoxic than the other aminoglycosides.

optimally. Clin Infect Dis. 2007 Sep 15;45(6):753–60. [PMID: 17712761]

Polymyxins

The polymyxins (colistin and polymyxin B) are basic polypeptides that are bactericidal for certain gram-negative aerobic rods, including *Pseudomonas.* Because of poor distribution into tissues and substantial toxicity (primarily nephrotoxicity and neurotoxicity), systemic use of these agents has been limited to infections caused by multidrug-resistant gram-negative organisms that are sensitive only to the polymyxins. Colistin has been used with increasing frequency in the treatment of pan-resistant *Acinetobacter baumanii* and *P aeruginosa*. In the treatment of cancer patients with multidrug-resistant *P aeruginosa*, colistin has been found to be more effective than other antibacterial options. The more recent experience suggests colistin to be associated with less nephrotoxicity and neurotoxicity than previously described. Dosage adjustments are required with kidney disease.

Hachem RY et al. Colistin is effective in treatment of infections caused by multidrug-resistant *Pseudomonas aeruginosa* in cancer patients. Antimicrob Agents Chemother. 2007 June;51(6):1905–11. [PMID: 17387153]

Antituberculous Drugs

Singular problems exist in the treatment of tuberculosis and other mycobacterial infections. The organisms are intracellular, have long periods of metabolic inactivity, and tend to develop resistance to any one drug. Therefore, combined drug therapy is used to delay the emergence of this resistance. First-line drugs, increasingly used together in all tuberculosis, are isoniazid, ethambutol, rifampin, and pyrazinamide.

See Chapter 9: Pulmonary Disorders for a discussion of these medications.

Alternative Drugs in Tuberculosis Treatment

The drugs listed alphabetically below are usually considered only in cases of drug resistance (clinical or laboratory) to first-line drugs.

Capreomycin is an injectable agent given intramuscularly in doses of 15–30 mg/kg/d (maximal dose 1 g). Major toxicities include ototoxicity (both vestibular and cochlear) and nephrotoxicity. If the drug must be used in older patients, the dose should not exceed 750 mg.

Clofazimine is a phenazine dye used in the treatment of leprosy and is active in vitro against *M avium* complex and *Mycobacterium tuberculosis*. It is given orally as a single daily dose of 100 mg for treatment of *M avium* complex disease. Its clinical efficacy for the therapy of tuberculosis has not been established. Adverse effects include nausea, vomiting, abdominal pain, and skin discoloration.

Cycloserine , a bacteriostatic agent, is given in doses of 15–20 mg/kg (not to exceed 1 g) orally and has been used in re-treatment regimens and for primary therapy of highly resistant *M tuberculosis*. It can induce a variety of central nervous system dysfunctions and psychotic reactions.

Ethionamide , like cycloserine, is bacteriostatic and is given orally in a dose of 15–20 mg/kg (maximal dose 1 g). It has been used in combination therapy but is poorly tolerated with marked gastric irritation.

The **fluoroquinolones** ofloxacin, levofloxacin, ciprofloxacin, and moxifloxacin are active in vitro against *M tuberculosis*, with MICs of 0.25–2 mcg/mL.

These drugs have been demonstrated to be efficacious in treating tuberculosis in patients unable to take isoniazid, rifampin, and pyrazinamide; however, rapid emergence of resistance has been described in some series. Doses include ciprofloxacin, 750 mg orally twice daily; ofloxacin, 400 mg orally twice daily; levofloxacin, 750 mg orally once daily.

Dye C. Doomsday postponed? Preventing and reversing epidemics of drug-resistant tuberculosis. Nat Rev Microbiol. 2009 Jan;7(1):81–7. [PMID: 19079354]

Rifamycins

In addition to its use as a primary agent in the treatment of tuberculosis, rifampin is used as an adjunct in the treatment of *S aureus* infections. When used as monotherapy, rifampin is associated with rapid emergence of resistance in staphylococci. However, when added to other primary antistaphylococcal agents, rifampin improves outcomes in the treatment of prosthetic hardware. Rifaximin, a derivative of rifamycin, is nonabsorbable, reaches very high levels in the stool, and has a broad spectrum of antibacterial activity, including aerobic and anaerobic gram-positive and gram-negative organisms. It is approved for use in nonpregnant women and for persons aged 12 years and older to treat noninvasive traveler's diarrhea (200 mg three times daily for 3 days) and should not be used if fever or bloody diarrhea is present. Rifamycins consistently display potent in vitro activity against *Clostridium difficile*, and small studies suggest rifaximin is useful, particularly in the treatment of patients with recurrent disease. Other potential uses include prophylaxis of traveler's diarrhea (200 mg/d) and therapy of hepatic encephalopathy (400 mg twice daily). It is well tolerated and safe.

Sulfonamides & Antifolate Drugs

Antimicrobial Activity

Sulfonamides are structural analogs of *p*-aminobenzoic acid (PABA) and compete with PABA to block its conversion to dihydrofolic acid. Organisms that utilize PABA in the synthesis of folates and pyrimidines are inhibited. Animal cells and some resistant microorganisms (eg, enterococci) use exogenous folate and thus are not affected by sulfonamides.

Trimethoprim and pyrimethamine are compounds that inhibit the conversion of dihydrofolic acid to tetrahydrofolic acid by blocking the enzyme dihydrofolate reductase. These two agents are generally used in combination with other drugs (usually sulfonamides) to prevent or treat a number of bacterial and parasitic infections. At high doses, all can inhibit mammalian dihydrofolate reductase, but clinically this is a problem only with pyrimethamine. Folinic acid (leucovorin) is given concurrently with pyrimethamine to reduce the risk of bone marrow suppression.

Sulfonamides alone are rarely used in the treatment of bacterial infection. When used in combination with other drugs, sulfonamides are useful in the treatment of toxoplasmosis and pneumocystosis.

The combination of trimethoprim (one part) plus sulfamethoxazole (five parts) is bactericidal for such gram-negative organisms as *E coli*, *Klebsiella*, *Enterobacter*, *Salmonella*, and *Shigella*, though substantial resistance has emerged. It is also active against many strains of *Serratia*, *Providencia*, *S maltophilia*, *B cepacia* (formerly *Pseudomonas cepacia*), and *Burkholderia pseudomallei*, but not against *P aeruginosa*. It is inactive against anaerobes and enterococci but inhibits most *Nocardia* and *S aureus* (including methicillin-resistant *S aureus*) and about 50% *S epidermidis*. *M catarrhalis*, *H influenzae*, *H ducreyi*, *L monocytogenes*, and some atypical mycobacteria are also inhibited by this combination.

Pharmacokinetics & Administration

Trimethoprim-sulfamethoxazole is well absorbed from the gastrointestinal tract and widely distributed in tissues and fluids, including cerebrospinal fluid, achieving similar serum levels with either intravenous or oral administration. Dosage adjustment is required for significant kidney disease (creatinine clearance 50 mL/min).

Clinical Uses

Present indications for sulfonamides are outlined below.

Urinary Tract Infections

Coliform bacteria, the most common cause of urinary tract infections, are moderately inhibited by sulfonamides, though widespread resistance of *E coli* has emerged. Short-course therapy (3 days) with oral double-strength trimethoprim-sulfamethoxazole (160 mg trimethoprim + 800 mg sulfamethoxazole) given twice daily is effective therapy for lower urinary tract infections in women who are symptomatic for less than 1 week. Since trimethoprim is concentrated in the prostate, trimethoprim-sulfamethoxazole, one double-strength tablet twice daily for 14–21 days, is effective in acute prostatitis. In chronic prostatitis, treatment for 6–12 weeks is indicated. Considering the above resistance trend, the routine use of trimethoprim-sulfamethoxazole for empiric therapy of urinary tract infections has been questioned. In those areas where resistance of *E coli* is greater than 10–20%, alternative agents should be used as empiric therapy. Considering the increased observation of community-acquired methicillin-resistant *S aureus*, trimethoprim-sulfamethoxazole has been recommended as a drug of choice in the treatment of this organism. Clinical and experimental reports demonstrate both success and failure using this agent. Despite these failures, trimethoprim-sulfamethoxazole is being used with increased frequency. Controlled clinical trials are warranted to clarify the role of this agent in the treatment of community-acquired methicillin-resistant

S aureus.

Parasitic Infections

Trimethoprim-sulfamethoxazole is effective for prophylaxis and treatment of *Pneumocystis* pneumonia, *Cyclospora* infection, and *Isospora belli* infection. For therapy of *Pneumocystis* pneumonia, 15–20 mg/kg/d of trimethoprim and 75–100 mg/kg/d of sulfamethoxazole in three or four divided doses is administered intravenously or orally—depending on the severity of disease—for 3 weeks. The dose for prophylaxis is 160 mg trimethoprim + 800 mg sulfamethoxazole daily or three times per week. (When given daily, it is also effective prophylaxis against toxoplasmal encephalitis.) *I belli* infection in HIV/AIDS has been successfully treated with 160 mg trimethoprim + 800 mg sulfamethoxazole orally four times daily for 10 days followed by twice-daily administration for 3 weeks. Cyclosporiasis is successfully treated with 160 mg trimethoprim and 800 mg sulfamethoxazole twice daily for 7–10 days. Sulfadiazine with pyrimethamine is also used to treat and prevent recurrence of toxoplasmosis.

Other Bacterial Infections

Sulfonamides are the drugs of choice for *Nocardia* infections. Trimethoprim-sulfamethoxazole is widely distributed in tissues, penetrates into the cerebrospinal fluid, and has been used to treat meningitis caused by gram-negative rods, though third-generation cephalosporins are now preferred. While it is occasionally used for outpatient respiratory tract infections, the increasing pattern of resistance associated with *S pneumoniae* has decreased its utility.

Trimethoprim-sulfamethoxazole is effective also for infections with *Enterobacter*, *B pseudomallei* (melioidosis), *S maltophilia*, or *B cepacia;* in combination with rifampin, for eradication of nasopharyngeal carriage of staphylococci; for prophylaxis against meningococcal disease when susceptible strains predominate; for antibacterial prophylaxis in organ transplant recipients or patients with chronic granulomatous disease; for treatment of *L monocytogenes* meningitis; and perhaps also for management of pulmonary Wegener granulomatosis.

Leprosy

Certain sulfones are widely used (see below).

Adverse Effects

Adverse reactions to sulfonamides occur in 10–15% of non-HIV/AIDS patients (usually a minor rash or gastrointestinal disturbance) and in up to 50% of patients with HIV/AIDS (predominantly rash, fever, neutropenia, and thrombocytopenia, often severe enough to require discontinuation of therapy). These drugs have many side effects—due partly to hypersensitivity, partly to direct toxicity—that must be considered whenever unexplained symptoms or signs occur in a patient who may have received these drugs.

Systemic Side Effects

Fever, skin rashes, urticaria; nausea, vomiting, or diarrhea; stomatitis, conjunctivitis, arthritis, aseptic meningitis, exfoliative dermatitis; bone marrow depression, thrombocytopenia, hemolytic anemia (in G6PD deficiency) or aplastic anemia, granulocytopenia, leukemoid reactions; hepatitis, polyarteritis nodosa, vasculitis, Stevens-Johnson syndrome; reversible hyperkalemia; and many others have been reported. Because of the risk of Stevens-Johnson syndrome, patients with a previous rash after trimethoprim-sulfamethoxazole should not receive the drug again. Patients reporting an allergic reaction to sulfonamides have an increased risk of allergy to penicillin.

HIV-positive patients intolerant to trimethoprim-sulfamethoxazole can often be desensitized. A 70% success rate has been reported after giving 0.004 mg trimethoprim/0.02 mg sulfamethoxazole as oral suspension and increasing the dose tenfold each hour to achieve a final dose of 160 mg trimethoprim/500 mg sulfamethoxazole.

Urinary Tract Disturbances

Older sulfonamides were relatively insoluble and would precipitate in urine. The most commonly used sulfonamides presently (sulfamethoxazole) are quite soluble, and the old admonition to force fluids is no longer warranted. Sulfonamides have been implicated in interstitial nephritis. Patients with toxoplasmosis receiving high-dose sulfadiazine therapy are predisposed to crystalluria.

Proctor RA. Role of folate antagonists in the treatment of methicillin-resistant *Staphylococcus aureus* infection. Clin Infect Dis. 2008 Feb 15;46(4):584–93. [PMID: 18197761]

Sulfones Used in the Treatment of Leprosy

A number of drugs closely related to the sulfonamides (eg, dapsone) have been used effectively in the long-term treatment of leprosy. The clinical manifestations of both lepromatous and tuberculoid leprosy can often be suppressed by treatment extending over several years. At least 5–30% of *Mycobacterium leprae* organisms are resistant to dapsone, so initial combined treatment with rifampin is advocated. Dapsone, 100 mg daily, is effective therapy for mild to moderate *Pneumocystis* pneumonia in AIDS when combined with trimethoprim, 20 mg/kg/d in four divided doses. At a dose of 50–100 mg daily or 100 mg two or three times a week, it is effective prophylaxis for *Pneumocystis jiroveci* (formerly *Pneumocystis carinii*) infection and, when combined with pyrimethamine, 50 mg per week, also prevents *Toxoplasma* encephalitis in HIV-infected patients.

Absorption, Metabolism, & Excretion

All sulfones are well absorbed from the intestinal tract, are distributed widely in all tissues, and tend to be retained in skin, muscle, liver, and kidney. Leprous skin contains ten times more drug than normal skin. Sulfones are excreted into the bile and reabsorbed by the intestine, prolonging therapeutic blood levels. Excretion into the urine is variable, and the drug occurs in urine mostly as a glucuronic acid conjugate.

Dosages & Routes of Administration

See Leprosy, in Chapter 33: Bacterial & Chlamydial Infections, for recommendations.

Adverse Effects

The sulfones may cause any of the side effects listed above for sulfonamides. Anorexia, nausea, and vomiting are common. Hemolysis, methemoglobinemia, or agranulocytosis may occur. G6PD levels should be determined prior to initiation of dapsone therapy. If sulfones are not tolerated, clofazimine can be substituted.

Bacitracin

This polypeptide is selectively active against gram-positive bacteria. Because of severe nephrotoxicity upon systemic administration, its use has been limited to topical application on surface lesions, usually in combination with polymyxin or neomycin.

Mupirocin

Mupirocin (formerly pseudomonic acid) is a naturally occurring antibiotic produced by *Pseudomonas fluorescens* active against most gram-positive cocci, including methicillin-sensitive and methicillin-resistant *S aureus* and most streptococci (but not enterococci). Used topically, it is effective in eliminating staphylococcal nasal carriage in the majority of patients for up to 3 months after application to the anterior nares twice daily for 5 days. However, recurrent colonization occurs (50% at the end of 1 year), and when mupirocin is used long-term over months, resistant organisms can emerge. High rates of mupirocin resistance have been observed in methicillin-resistant *S aureus* isolates from surgical intensive care unit patients, despite minimal in-hospital mupirocin use. This finding suggests the benefit of mupirocin is limited. Monthly application for 5 days each month for up to a year decreases staphylococcal colonization, which in turn lowers the risk of recurrent staphylococcal skin infections. Recent studies demonstrate an associated reduction in postoperative staphylococcal lung infections in colonized patients treated with mupirocin. Whether it is more effective than trimethoprim-sulfamethoxazole or dicloxacillin plus rifampin for eradication of staphylococcal nasal carriage is unknown. The other major use of mupirocin is for therapy of impetigo; it is useful in mild disease.

Clindamycin

Clindamycin is active against gram-positive organisms including *S pneumoniae*, viridans streptococci, group A streptococci, and *S aureus*, though resistance has been described in all of these organisms. Pneumococci or staphylococci with an efflux-based mechanism of resistance can be effectively treated with clindamycin. However, isolates with ribosomal methylase resistance (about 10% of isolates) are also resistant to clindamycin. Enterococci and most *S epidermidis* also are resistant. However, at the present time, most community-acquired methicillin-resistant *S aureus* (caMRSA) are susceptible to clindamycin. In those instances in which caMRSA isolates demonstrate resistance to macrolides but susceptibility to clindamycin, additional microbiologic testing ("D" test) is advised to confirm the effectiveness of clindamycin. A dosage of 0.15–0.3 g every 6 hours is generally given when the oral route is used. It is widely distributed in tissues but not in cerebrospinal fluid. Excretion is primarily nonrenal. Clindamycin is currently recommended as an alternative drug for prophylaxis against endocarditis following certain dental procedures in patients allergic to amoxicillin. Clindamycin, 300 mg orally twice daily for 7 days, can be used as an alternative to metronidazole for the therapy of bacterial vaginosis. Topical application of a 2% vaginal cream once or twice daily for 7 days is also effective. Clindamycin is active against most anaerobes, including *Prevotella*, *Clostridium*, *Peptococcus*, *Peptostreptococcus*, and *Fusobacterium* organisms. However, up to 25% of *Bacteroides* isolates are resistant, and alternative agents should be considered for serious infections due to these organisms. It is frequently used to treat less severe infections in which anaerobes are significant pathogens (eg, aspiration pneumonia, pelvic and abdominal infections), often in combination with other drugs (aminoglycosides, cephalosporins, fluoroquinolones). Patients with hospital-acquired infection should be given clindamycin, 600–900 mg (20–30 mg/kg/d) intravenously every 8 hours. It has also been of use in staphylococcal osteomyelitis, particularly in children. Because tissue models document that clindamycin significantly decreases toxin production, the addition of clindamycin to penicillin for therapy of group A streptococcus toxic shock syndrome is often used. In the sulfonamide-allergic patient, high-dose clindamycin therapy (600–1200 mg intravenously every 6 hours or 600 mg orally every 6 hours) in conjunction with pyrimethamine has been used to treat toxoplasmosis of the central nervous system and appears to be as effective as pyrimethamine and sulfadiazine. Clindamycin in combination with primaquine is effective in *Pneumocystis* pneumonia, and clindamycin with quinine is of value for falciparum malaria. While useful in brain abscess, clindamycin is ineffective in meningitis.

Common side effects are diarrhea, nausea, and skin rashes. Antibiotic-associated colitis has been associated with the administration of clindamycin and other antibiotics and is due to a necrotizing toxin produced by *Clostridium difficile.* The organism is resistant to the antimicrobial, is selected out by its presence, and is favored in its growth and toxin production. Interestingly, the more recent hypervirulent strain of *C difficile* is not associated with clindamycin. Rather, antecedent receipt of fluoroquinolones is a significant risk factor. *C difficile* is usually susceptible to—and can be treated with—metronidazole or vancomycin given orally (see below).

Metronidazole

Metronidazole is an antiprotozoal drug (see Chapter 35: Protozoal & Helminthic Infections) also active against most anaerobic gram-negative bacilli (ie, *Bacteroides*, *Prevotella*, *Fusobacterium*) as well as *Clostridium* species but has minimal activity against many anaerobic gram-positive and microaerophilic organisms. It is well absorbed after oral administration and is widely distributed in tissues. It penetrates well into the cerebrospinal fluid, yielding levels similar to those in serum. The drug is metabolized in the liver, and dosage reduction is required in severe hepatic insufficiency or biliary dysfunction.

Metronidazole is used to treat amebiasis and giardiasis (see Chapter 35: Protozoal & Helminthic Infections) and in the following circumstances:

1. Vaginitis caused by *Trichomonas vaginalis* responds to either a single dose (2 g) or to 250 mg

orally three times daily for 7–10 days. Bacterial vaginosis responds to a single 2-g dose or to 500 mg twice daily for 7 days. Metronidazole vaginal cream (0.75%) applied twice daily for 5 days is also effective.

2. In anaerobic infections, metronidazole can be given orally or intravenously, 500 mg three times daily (30 mg/kg/d). In contrast to clindamycin or second-generation cephalosporins, metronidazole is active against virtually 100% of *B fragilis* isolates.

3. Metronidazole is less expensive and equally as efficacious as oral vancomycin for the therapy of *C difficile* colitis and is the drug of choice for mild to moderate disease. A dosage of 500 mg orally three times daily is recommended. If oral medication cannot be administered, intravenous metronidazole can be tried at the same dose; however, the efficacy associated with this route is unproven and usually less effective than the oral one. Because of the emergence of vancomycin-resistant enterococci as a major pathogen and the role of oral vancomycin in selecting for these resistant organisms, metronidazole should be used as first-line therapy for *C difficile* disease. While metronidazole and vancomycin are equally effective in the treatment of mild to moderate *C*

difficile disease, oral vancomycin is superior to metronidazole in the treatment of severe disease.

4. Preparation of the colon before bowel surgery.
5. Therapy of brain abscess, often in combination with penicillin or a third-generation cephalosporin.
6. In combination with clarithromycin and omeprazole for therapy of *H pylori* infections.

Adverse effects include stomatitis, nausea, and diarrhea. Ingestion of alcohol while taking metronidazole occasionally results in a disulfiram reaction. With prolonged use at high doses, reversible peripheral neuropathy can develop. Metronidazole can decrease the metabolism of warfarin, necessitating dosage adjustment of warfarin. Metronidazole is carcinogenic in certain animal models and mutagenic for certain bacteria, but to date an increased incidence of malignancy has not been confirmed in humans.

Zar FA et al. A comparison of vancomycin and metronidazole for the treatment of *Clostridium difficile*-associated diarrhea, stratified by disease severity. Clin Infect Dis. 2007 Aug 1;45(3):302–7. [PMID: 17599306]

Vancomycin

This drug is bactericidal for most gram-positive organisms, particularly staphylococci and streptococci, and is bacteriostatic for most enterococci. While active against staphylococci, vancomycin kills more slowly when compared with nafcillin. Although vancomycin has retained activity against staphylococci and streptococci, vancomycin-resistant strains of enterococci (particularly *E faecium*) have emerged. *S aureus* both intermediately sensitive and highly vancomycin-resistant has been observed in patients receiving long-term vancomycin therapy. Vancomycin is not absorbed from the gastrointestinal tract. It is given orally only for the treatment of antibiotic-associated enterocolitis. For systemic effect, the drug must be administered intravenously (20–30 mg/kg/d in two or three divided doses). Vancomycin is excreted mainly via the kidneys. In kidney disease, the half-life may be up to 8 days. Vancomycin is cleared via high-flux hemodialysis and continuous arteriovenous hemofiltration (CAVH) generally resulting in the need for increased dosing. In patients with impaired kidney function, the dosing interval is determined by measuring trough serum levels. When trough serum levels decline to 10–15 mcg/mL, repeat dosing is required. Recent guidelines have suggested more aggressive dosing with associated troughs of > 15 mcg/mL in the treatment of methicillin-resistant *S aureus* ventilator-associated pneumonia. However, the association of attainment of these elevated trough levels and efficacy has not been proven. Large doses (4 g daily) have been associated with mild nephrotoxicity.

Indications for parenteral vancomycin include the following: (1) Severe staphylococcal infections in penicillin-allergic patients; for methicillin-resistant *S aureus* and *S epidermidis* infections and for serious infections (pneumonia, meningitis) due to highly resistant *S pneumoniae.* While no clinical trials have suggested vancomycin to be superior to alternative agents, such as linezolid and daptomycin, some trials suggest vancomycin to be inferior. Vancomycin failure in the treatment of serious methicillin-resistant *S aureus* infection has been associated with those isolates with an MIC of 2 mcg/mL; alternative antibacterials are recommended for such isolates. (2) Severe enterococcal infections in the penicillin-allergic patient or if the enterococcus is penicillin-resistant. (3) Other gram-positive infections in penicillin-allergic patients, eg, viridans streptococcal endocarditis. (4) Surgical prophylaxis in penicillin-allergic patients. (5) For gram-positive infections due to organisms that are multidrug-resistant, ie, *Corynebacterium jeikeium*. (6) Endocarditis prophylaxis in the penicillin-allergic patient. In antibiotic-associated enterocolitis, vancomycin, 0.125 g, is given orally four times daily. Oral vancomycin is preferred over oral metronidazole in the treatment of severe *C difficile* disease.

Thrombophlebitis sometimes follows intravenous injection. The drug is infrequently ototoxic when given concomitantly with aminoglycosides or high-dose intravenous erythromycins; it is potentially nephrotoxic when administered with aminoglycosides. Some studies suggest larger vancomycin doses to be associated with an increased incidence of nephrotoxicity. Rapid infusion or high doses (1 g or more) may induce diffuse hyperemia ("red man syndrome") and can be avoided by extending infusions over 1–2 hours, by reducing the dose, or by pretreating with a histamine antagonist such as hydroxyzine.

15;44(12):1543–8. [PMID: 17516396]

Lodise TP et al. Larger vancomycin doses (at least four grams per day) are associated with an increased incidence of nephrotoxicity. Antimicrob Agents Chemother. 2008 Apr;52(4):1330–6. [PMID: 18227177]

Soriano A et al. Influence of vancomycin minimum inhibitory concentration on the treatment of methicillin-resistant *Staphylococcus aureus* bacteremia. Clin Infect Dis. 2008 Jan 15;46(2):193–200. [PMID: 18171250]

Streptogramins

Synercid, the one approved streptogramin, is a combination of two synthetic derivatives of pristinamycin—quinupristin and dalfopristin—in a 30:70 ratio that is administered intravenously. It is bactericidal and inhibits protein synthesis by binding to bacterial ribosomes. Its major clinical use is in the therapy of gram-positive infections, particularly methicillin-resistant *S aureus* and *S epidermidis* and enterococci, including vancomycin-resistant *E faecium.* The combination is not reliably active against *E faecalis.* The recommended dose is 7.5 mg/kg/dose intravenously every 8 hours. In addition to phlebitis with peripheral administration, the major adverse effect is arthralgias and myalgias, which resolve with discontinuation of the drug. It is primarily cleared via the liver; streptogramins inhibit the cytochrome P450 system, resulting in increased levels of cyclosporine and other agents. With the availability of linezolid and daptomycin, the indications for this agent are extremely limited.

Oxazolidinediones

Oxazolidinediones represent a class of antibacterials of which linezolid is the one available agent. Linezolid is primarily active against aerobic gram-positive pathogens, including penicillin-resistant pneumococci, methicillin-resistant staphylococci and enterococci (both *E faecalis* and vancomycin-sensitive and vancomycin-resistant *E faecium*). Linezolid is bacteriostatic against all of these pathogens. Linezolid-resistant and vancomycin-resistant enterococci and linezolid-resistant *S aureus* have been observed, however. The oral bioavailability of linezolid is complete, with serum levels approaching those observed with intravenous administration. The drug is eliminated primarily by nonrenal mechanisms. The primary toxicity is bone marrow suppression with long-term therapy, particularly the platelet line. Other adverse effects include neuropathy and mitochondrial toxicity with long-term use. Linezolid is a mild monoamine oxidase inhibitor and while concomitant use of selective serotonin reuptake inhibitors may result in a serotonin syndrome, most patients can safely receive both agents together. In the treatment of methicillin-resistant *S aureus* pneumonia, studies suggest improved clinical response with linezolid when compared with vancomycin; however, these findings require confirmation through prospective controlled studies. Of particular concern are the increasing reports of linezolid-resistant *Enterococcus and staphylococci*, which reinforce that this agent should be used judiciously.

Daptomycin

Daptomycin is a bactericidal lipopeptide with a spectrum of activity similar to that of linezolid or quinupristin-dalfopristin. This spectrum includes methicillin-resistant staphylococci and vancomycin-resistant enterococci; however, MICs are much lower for the former than the latter. Daptomycin has poor oral bioavailability, thus is only available as a parenteral product. Its long pharmacologic half-life allows for once-daily dosing (4 mg/kg every 24 hours in skin and soft tissue infection and 6 mg/kg every 24 hours in the treatment of bacteremia and right-sided endocarditis); dosage adjustment is necessary in the presence of kidney disease. Up to 10 mg/kg daily has been used to treat serious infection, particularly that associated with enterococcus. The primary adverse event associated with daptomycin is a reversible, dose-dependent myopathy observed with > 7 days of therapy. Daptomycin cannot be used in the treatment of respiratory tract infection because pulmonary surfactant binds daptomycin, resulting in minimal free drug concentrations in pulmonary secretions.

Quinolones

The quinolones are synthetic analogs of nalidixic acid with a broad spectrum of activity against many bacteria. The mode of action of all quinolones involves inhibition of bacterial DNA synthesis by blocking the enzyme DNA gyrase.

The earlier quinolones (nalidixic acid, oxolinic acid, cinoxacin) did not achieve systemic antibacterial levels after oral intake and thus were useful only as urinary antiseptics. The fluoroquinolone derivatives (ciprofloxacin, levofloxacin, gemifloxacin, and moxifloxacin) have more potent antibacterial activity, achieve clinically useful levels in blood and tissues, and have low toxicity.

Antimicrobial Activity

A number of fluoroquinolones are in use. With a few exceptions, the spectrum of activity is similar among the available agents. In general, these drugs have moderate to excellent activity against Enterobacteriaceae but are also active against other gram-negative bacteria such as *Haemophilus*, *Neisseria*, *Moraxella*, *Brucella*, *Legionella*, *Salmonella*, *Shigella*, *Campylobacter*, *Yersinia*, *Vibrio*, and *Aeromonas* organisms. Resistance to *E coli* has significantly increased over the past decade, with some centers reporting up to 20–30% resistance. Ciprofloxacin and levofloxacin are the only agents with activity against *P aeruginosa*, but the increasing resistance of *P aeruginosa* to fluoroquinolones has limited their utility. None of these agents have reliable activity against *S maltophilia* or *B cepacia* or against certain genital tract pathogens, such as *Mycoplasma hominis, U urealyticum,* and *Chlamydophila pneumoniae. M tuberculosis* is sensitive to the quinolones, as is *M fortuitum* and *Mycobacterium kansasii.*

In general, the fluoroquinolones are less potent against gram-positive than against gram-negative organisms. Gemifloxacin, levofloxacin, and moxifloxacin have the best gram-positive activity, including against pneumococci and strains of *S aureus* and *S epidermidis*, including some methicillin-resistant strains. However, the emergence of resistant strains of staphylococci has limited the use of these drugs in infections caused by these organisms. Use of fluoroquinolones to treat tuberculosis in South Africa has been associated with emergence of invasive disease due to levofloxacin non-susceptible *S pneumoniae*. Enterococci, including *E faecalis, S pneumoniae*, group A, B, and D streptococci, and viridans streptococci, are only moderately inhibited by the older quinolones. *T pallidum* and *Nocardia* are resistant.

Moxifloxacin demonstrates modest activity against many of the significant anaerobic pathogens, including *B fragilis* and mouth anaerobes, and is approved for the treatment of intra-abdominal infection. However, increased rates of anaerobic resistance over time have been reported.

Pharmacokinetics & Administration

After oral administration, the fluoroquinolones are well-absorbed and widely distributed in body fluids and tissues and are concentrated intracellularly. Fluoroquinolones bind some heavy metals; thus, absorption is inhibited when administered concomitantly with iron, calcium, and other multivalent cations. Optimal oral bioavailability is achieved if fluoroquinolones are taken 1 hour before or 2 hours after meals. The serum half-life ranges from 4 hours (ciprofloxacin) to 12 hours (moxifloxacin). After ingestion of 500 mg, the peak serum level of ciprofloxacin is 2.5 mcg/mL, which is lower than that of the other quinolones (4–6 mcg/mL), but this is offset by ciprofloxacin's slightly greater in vitro potency against most gram-negative organisms. A number of the fluoroquinolones can be administered intravenously, resulting in peak serum levels ranging from 4 mcg/mL to 9 mcg/mL (see Table 30–8). Most are eliminated via mixed renal and nonrenal pathways. As a result, only modest accumulation takes place in the presence of kidney disease. Exceptions are ofloxacin and levofloxacin, which are primarily dependent upon the kidney for elimination.

Clinical Uses

Urinary tract infections caused by trimethoprim-sulfamethoxazole–resistant gram-negative organisms have resulted in quinolones being recognized as potential drugs of choice in areas with > 10–20% resistance of *E coli* to trimethoprim-sulfamethoxazole.

Because of good penetration into prostatic tissue, quinolones are effective in treating bacterial prostatitis and are alternatives to trimethoprim-sulfamethoxazole (doses for prostatitis are the same as for urinary tract infection, but the duration should be 6–12 weeks).

Quinolones are approved for treatment of certain sexually transmitted diseases. Ofloxacin, 300 mg orally twice daily for 7 days, is as effective as doxycycline, 100 mg orally twice daily for 7 days, for the therapy of *C trachomatis* cervicitis, urethritis, and proctitis. It is also effective for nongonococcal urethritis caused by *U urealyticum*. Ciprofloxacin is not effective for the therapy of chlamydial infections or nongonococcal urethritis. In general, the use of quinolones for the treatment of any sexually transmitted disease will be limited by their lack of efficacy with concomitant syphilis. While gonococcal urethritis, cervicitis, pharyngitis, and proctitis can be treated with a single oral dose of 500 mg of ciprofloxacin or 400 mg of oral ofloxacin, the increased prevalence of quinolone-resistant gonococci in the United States has resulted in the CDC no longer recommending these agents in the treatment of gonorrhea. Ceftriaxone and certain oral cephalosporins are the CDC-recommended therapy of *Neisseria gonorrhoeae*.

Pelvic inflammatory disease is usually caused by *C trachomatis, N gonorrhoeae*, Enterobacteriaceae, or anaerobes. Considering the high rate of fluoroquinolone-resistant *N gonorrhoeae*, regimens involving these agents are recommended as alternative regimens only in those patients unable to tolerate parenteral ceftriaxone, cefoxitin, or cefotetan. Oral outpatient treatment with ofloxacin, 400 mg twice daily (or levofloxacin 500 mg once daily) for 14 days with or without metronidazole, 500 mg orally twice daily for 14 days, can be used. Epididymitis in young men (< 35 years of age) is caused most commonly by *Chlamydia* and the gonococcus. While intramuscular ceftriaxone plus oral doxycycline is the regimen of choice for acute epididymitis most likely caused by enteric organisms or with negative gonococcal culture or nucleic acid amplification test, levofloxacin, 500 mg orally once daily, (or ofloxacin, 300 mg orally twice daily) for 10 days, can be used. Fluoroquinolones have been used successfully to treat complicated skin and soft tissue infections and osteomyelitis caused by gram-negative organisms. Ciprofloxacin, 500–750 mg orally twice daily for at least 6 weeks, has been effective therapy for malignant otitis externa.

Quinolones are among the few oral agents active against *Campylobacter;* however resistance has been steadily increasing. In addition, they are active against the other major bacterial pathogens associated with diarrhea *(Salmonella*, *Shigella*, toxigenic *E coli)*. Consequently, they have been used for the therapy of traveler's diarrhea as well as domestically acquired acute diarrhea. Norfloxacin, ciprofloxacin, and ofloxacin may be effective in eradicating the chronic carrier state of *Salmonella* when therapy is continued for 4–6 weeks.

Ciprofloxacin has been used to eradicate meningococci from the nasopharynx of carriers.

Fluoroquinolones are effective for prophylaxis against gram-negative infections in the neutropenic patient, and intravenous ciprofloxacin in combination with -lactam antibiotics has been used successfully to treat febrile neutropenia.

Gemifloxacin, levofloxacin, and moxifloxacin are sometimes referred to as "respiratory fluoroquinolones" due to their activity against the pneumococci, including penicillin-resistant strains as well as atypical respiratory bacteria. However, their broad aerobic gram-negative spectrum suggests that they should be reserved for the treatment of refractory infections or high-risk patients, including those with comorbidities or with recent receipt of -lactam antibacterials. One setting in which ciprofloxacin is indicated for the therapy of lower respiratory tract infections is in cystic fibrosis, in which *P aeruginosa* is the predominant pathogen. However, the increasing rate of resistance to ciprofloxacin has diminished the use of the drug for this indication.

Ciprofloxacin in combination with other agents has been used to treat *M avium* complex infections, and ciprofloxacin, levofloxacin, ofloxacin, and moxifloxacin may be efficacious in the therapy of multidrug-resistant tuberculosis.

Adverse Effects

The most prominent adverse effects of the quinolones are nausea, vomiting, and diarrhea. Occasionally, headache, dizziness, seizures, insomnia, impaired liver function, and skin rashes have been observed as well as more serious reactions such as acute kidney injury, hypoglycemia (especially with gatifloxacin, which has been removed from the US market), and anaphylaxis. Fluoroquinolones as a class prolong the QT interval; it is debated whether any one agent is implicated more than another. Quinolones should be used cautiously in patients receiving antiarrhythmics such as amiodarone or in persons with a history of prolonged QT. Prolongation of the prothrombin time and the international normalized ratio has been observed in some patients receiving stable doses of warfarin after ciprofloxacin has been given, but this interaction is unpredictable and modest. Tendinitis and tendon rupture have been reported with quinolone agents. Risk factors include concomitant corticosteroid use and age > 60 years. The FDA has approved a black box warning for tendinopathy. Patients experiencing musculoskeletal symptoms while receiving fluoroquinolones should discontinue therapy.

for multidrug-resistant tuberculosis in children in South Africa: a cohort observational surveillance study. Lancet. 2008 Mar 29;371(9618):1108–13. [PMID: 18359074]

Pentamidine & Atovaquone

Pentamidine and atovaquone are antiprotozoal agents that are primarily used to treat *Pneumocystis* pneumonia. Pentamidine is discussed in Chapter 31: HIV Infection & AIDS and Chapter 35: Protozoal & Helminthic Infections. Atovaquone inhibits mitochondrial electron transport and probably also folate metabolism. The solid dosage form is poorly absorbed and should be given with food to maximize bioavailability. The suspension is significantly better absorbed and preferred especially in high-risk patients (those with diarrhea, malabsorption). It has moderate activity against *P jiroveci*. In comparative trials with trimethoprim-sulfamethoxazole and pentamidine in the therapy of *Pneumocystis* pneumonia in AIDS, atovaquone, 750 mg orally three times daily for 3 weeks, is less effective than both agents but better tolerated. It has also been used as prophylaxis in AIDS patients at a dosage of 1500 mg daily. Major adverse effects include rash, nausea, vomiting, diarrhea, fever, and abnormal liver function tests. The use of atovaquone is limited to patients with mild to moderate

Pneumocystis infections who have not responded to or cannot tolerate other therapies.

Urinary Antiseptics

These drugs exert antimicrobial activity in the urine but have little or no systemic antibacterial effect. Their usefulness is limited to therapy and prevention of urinary tract infections.

Nitrofurantoin

Nitrofurantoin is active against the common gram-positive urinary pathogens *E faecalis* and *Staphylococcus saprophyticus*, but the drug inhibits only about 50% of *E faecium.* It is also used against *E coli* and *Citrobacter,* but activity against *Proteus, Serratia,* and *Pseudomonas* is poor. Following oral administration, about 50% of the drug is absorbed, but serum concentrations are very low and tissue levels are undetectable. Levels in the urine reach concentrations of 200–400 mcg/mL, which are well above the MICs of susceptible organisms. However, in kidney disease, subtherapeutic urine levels are present and drug accumulation takes place in serum. Given low serum levels, poor tissue penetration, and renal elimination, the use of nitrofurantoin is limited to therapy or prophylaxis of cystitis in patients with normal kidney function. Nitrofurantoin cannot be used to treat pyelonephritis or prostatitis.

The average daily dose in urinary tract infections is 100 mg orally four times daily, taken with food. The macrocrystal preparation can be given at a dosage of 100 mg twice daily. A single daily dose of 50–100 mg can prevent recurrent urinary tract infections in women.

Oral nitrofurantoin often causes nausea and vomiting. The crystalline formulation is better tolerated than previous preparations. Hemolytic anemia may occur in G6PD deficiency. Other side effects are skin rashes and, uncommonly, peripheral neuropathy. Acute and chronic pulmonary hypersensitivity reactions may occur, and pulmonary fibrosis has occurred with prolonged use.

Fosfomycin

Fosfomycin tromethamine is a phosphonic acid derivative useful in the treatment of uncomplicated urinary tract infection. The spectrum of activity includes *E coli*, *E faecalis*, and other gram-negative aerobic urinary pathogens, but not *P aeruginosa*. Available as a 3-g sachet, fosfomycin may be useful for the single-dose treatment of the above organisms. Like nitrofurantoin, fosfomycin should not be used for systemic infection. However, the increased concentrations in urine allow for its use in uncomplicated bacteriuria. In contrast, fosfomycin disodium is available in Europe for intravenous use and may be useful in the treatment of more serious infections. The most frequently reported adverse effects include diarrhea, headache, and nausea.

Falagas ME et al. Fosfomycin: use beyond urinary tract and gastrointestinal infections. Clin Infect Dis. 2008 Apr 1;46(7):1069–77. [PMID: 18444827]

Antifungal Drugs

Empiric antifungal therapy is rarely instituted except for febrile neutropenic and other high-risk patients. Therapy generally is reserved for situations in which yeast or mold is seen on KOH preparation or when isolated organisms are thought to be pathogenic. Antifungal standardized susceptibility testing is available for *Candida* spp, and predict clinical outcome. In contrast, susceptibility testing for most other fungi is not generally available; in vitro results for these pathogens is less predictive of patient outcomes.

Amphotericin B

Amphotericin B in vitro inhibits several organisms producing systemic mycotic disease in humans, including *Aspergillus*, *Histoplasma*, *Cryptococcus*, *Coccidioides, Candida, Blastomyces, Sporothrix,* and others. This drug can be used for treatment of these systemic fungal infections. *Pseudallescheria boydii* and *Fusarium* are often resistant to amphotericin B.

There is no consensus on how conventional amphotericin B should be administered or on the dosage and the duration of therapy. A test dose is unnecessary, since anaphylaxis is extremely rare. The daily dose of amphotericin B for most fungal infections varies from 0.3 mg/kg to 0.7 mg/kg, though infections caused by *Aspergillus* and *Mucor* are often treated with 1–1.5 mg/kg daily.

Combined treatment with flucytosine is beneficial in cryptococcal meningitis and possibly systemic candidiasis. Amphotericin B may have some benefit in *Naegleria* meningoencephalitis.

Amphotericin B has been used prophylactically to prevent invasive fungal infections in bone marrow transplant recipients; however, other agents are less toxic and may be more efficacious. Whether prophylactic antifungal use is better than early empiric therapy in febrile patients who have not responded to broad-spectrum antibiotics has not been determined.

In patients with Foley catheters in place who have candiduria, amphotericin B bladder irrigations decrease colony counts; however, the efficacy of irrigation is marginal, and long-term eradication of candiduria following amphotericin B bladder irrigation rarely occurs.

Neither kidney disease nor liver failure alters the pharmacokinetic disposition of amphotericin. The drug concentrates in the lung, liver, spleen, and kidney with minimal penetration into skin or adipose tissue. The drug is not removed by hemodialysis.

The intravenous administration of amphotericin B often produces chills, fever, vomiting, and headache. As a rule, infusions given over 1–2 hours are as well tolerated as those given over 4–6 hours. However, patients who experience infusion-related adverse effects may benefit from slowing the rate of administration. Tolerability may be enhanced by temporary lowering of the dose or premedication with acetaminophen and diphenhydramine. Addition of 25 mg of hydrocortisone to the infusion decreases the incidence of rigors, and meperidine, 25–50 mg, is effective in arresting rigors once they start. Central intravenous administration eliminates the likelihood of thrombophlebitis. Electrolyte disturbances (hypokalemia, hypomagnesemia, distal renal tubular acidosis) also commonly occur. Kidney injury can be reduced with sodium supplementation. As a result, administration of 0.5–1 L of 0.9% saline prior to infusion of amphotericin B is recommended.

The nephrotoxicity of amphotericin has resulted in the development of lipid-based amphotericin B products. The most commonly used agents are amphotericin B lipid complex (ABLC; Abelcet) and liposomal amphotericin B (L-AmB; AmBisome). Complexing amphotericin B with lipid allows larger doses to be administered (3–6 mg/kg, depending on the preparation and the fungal species). Liposomal amphotericin 10 mg/kg/d is no better than 3 mg/kg/d in the treatment of invasive mold infection; however, the larger dose is associated with significantly increased nephrotoxicity. The lipid formulations are particularly effective for treatment of visceral leishmaniasis. Short courses (5–10 days) with low doses (2–4 mg/kg/d depending on which preparation is used) are very effective in eradicating the parasite, probably because of distribution of the drug to the reticuloendothelial system, the major site of parasite invasion.

These preparations are associated with less nephrotoxicity than conventional amphotericin B. Liposomal amphotericin is somewhat less nephrotoxic than ABLC. Infusion-related adverse effects are variable, with liposomal amphotericin the best tolerated. Liposomal amphotericin is equal to or better than that of conventional amphotericin B in febrile neutropenia, particularly in prevention of emergent *Candida* infections.

Drug acquisition costs for lipid-based products are much greater than for conventional amphotericin B. The availability of lipid-based amphotericin, echinocandins and triazoles has resulted in a greatly reduced role for conventional amphotericin for the prevention and treatment of fungal infection.

Cornely OA et al. Liposomal amphotericin B as initial therapy for invasive mold infections: a randomized trial comparing a high-loading dose regimen with standard dosing (AmBiLoad Trial). Clin Infect Dis. 2007 May 15;44(10):1289–97. [PMID: 17443465]

Nystatin

Nystatin has a wide spectrum of antifungal activity but is used almost exclusively to treat superficial candidal infections. It is too toxic for systemic administration, and the drug is not absorbed from mucous membranes or the gastrointestinal tract. Several preparations are available, including oral suspension (100,000 units/mL) and ointments, gels, and creams (100,000 units/g). For oral candidiasis, 500,000 units of suspension is used as a "swish and swallow" and repeated four times a day for at least 2 days after resolution of the infection. Infections of skin are treated with cream or ointment, 100,000 units applied to the affected area twice daily until resolution of the infection.

Flucytosine

Flucytosine inhibits some strains of *Candida*, *Cryptococcus*, *Aspergillus*, and other fungi. Dosages of 3–8 g daily (75–150 mg/kg/d) orally produce therapeutic levels in serum, urine, and cerebrospinal fluid. When used as monotherapy, development of resistance is common; thus, flucytosine is not used as a single drug therapy except in candiduria.

In kidney disease, flucytosine may accumulate to toxic levels, and dosage adjustment is needed. Because patients with HIV infection and normal kidney function do not tolerate the previously used doses of flucytosine (150 mg/kg/d in four divided doses), 75–100 mg/kg/d is recommended. The drug is effectively removed by hemodialysis. Toxic effects include bone marrow depression, abnormal liver function, and nausea. Bone marrow suppression is caused by conversion of flucytosine to fluorouracil. Combined use of flucytosine and amphotericin B in cryptococcal meningitis and possibly systemic candidiasis has been shown to be of value.

Natamycin

Natamycin is a polyene antifungal drug effective against many different fungi in vitro. When it is combined with appropriate surgical measures, topical application of 5% ophthalmic suspension may be beneficial in the treatment of keratitis caused by *Fusarium*, *Acremonium* (cephalosporium), or other fungi. The toxicity after topical application appears to be low.

Terbinafine

Terbinafine, an allylamine, inhibits fungal cell membrane function by blocking ergosterol synthesis. Terbinafine is available topically as well as in 250-mg tablets for oral administration. The recommended dosage is 250 mg daily for 12 weeks for toenail infections and 250 mg daily for 6 weeks for fingernail infections (success rate about 70%). Pulse therapy (1 week on and 3 weeks off) is as effective as continuous therapy for 6–12 weeks. The drug also is active against many strains of *Candida* and *Aspergillus* organisms and has been used in combination with other antifungals to treat severe infections with these pathogens. Most adverse effects are minor (diarrhea, dyspepsia) or transient (taste disturbance). Rare cases of severe hepatic injury have occurred.

Antifungal Imidazoles & Triazoles

These antifungal drugs inhibit synthesis of ergosterol, resulting in inhibition of membrane-associated enzyme activity, cell wall growth, and replication.

Clotrimazole , taken orally in the form of 10-mg troches five times daily, can prevent and treat oral candidiasis. Vaginal azole tablets inserted daily for 1–7 days are effective for vaginal candidiasis. Topical preparations for treatment of cutaneous dermatophytes are also available.

Fluconazole , a bis-triazole with activity similar to that of ketoconazole, is water-soluble and can be given both orally and intravenously. Absorption of the drug after oral administration is not pH-dependent. It penetrates well into the cerebrospinal fluid and eye. The drug has been shown to be effective primarily in the treatment of *Candida*, *Cryptococcus*, and *Blastomyces* infections. *Candida albicans*, *C tropicalis*, and *C parapsilosus* are usually sensitive to fluconazole, but many other species of *Candida* (*C krusei*, *C glabrata*, etc) are often resistant. Fluconazole-resistant strains of *C albicans* primarily have been observed in HIV/AIDS patients receiving long-term fluconazole therapy. With the advent of highly active antiretroviral therapy, the rate of fluconazole resistance in *C albicans* has decreased in this patient population. The drug is inactive against *Aspergillus*, *Mucor*, and *Pseudallescheria*. Fluconazole is effective in oropharyngeal candidiasis and candidal esophagitis in immunosuppressed patients. It is as effective or more effective than vaginal creams and suppositories in vaginal candidiasis; a single oral dose of fluconazole 150 mg is 80–90% effective. Fluconazole, 400 mg intravenously and orally daily, is as effective as amphotericin B, 0.5–0.6 mg/kg/d, for candidemia in both neutropenic and nonneutropenic patients. Most of these infections are intravenous line–related, and removal of the line is critical to successful therapy. Fluconazole (200 mg/d) is effective as long-term suppressive therapy of cryptococcal meningitis in patients with HIV/AIDS and is the drug of choice in this setting. In the treatment of cryptococcal meningitis, response rates and overall mortality rates are the same in patients treated with oral fluconazole and with amphotericin B. However, the mortality rate in the first 2 weeks is higher with fluconazole and sterilization of cerebrospinal fluid is slower with fluconazole. Consequently, induction generally takes place with amphotericin B for 2 weeks, followed by oral fluconazole. A dosage of 400 mg of fluconazole daily is effective therapy for coccidioidal meningitis (80% response), but improvement is slow, taking as long as 4–8 months. Increased doses (800–1200 mg/d) have been used; however, they have not been found to be superior to usual doses. Fluconazole, 400 mg daily, is effective prophylaxis against superficial and invasive fungal infections in bone marrow and liver transplant recipients, but concern has been raised about superinfection with resistant organisms (*C krusei*, *C glabrata*, *Aspergillus).* Because the overall incidence of invasive fungal disease in HIV infection is low, universal prophylaxis to prevent disease is discouraged, especially with the advent of more potent antiretroviral therapy. Fluconazole is also effective for the therapy of cutaneous leishmaniasis due to *Leishmania major* in a dose of 200 mg/d for 6 weeks.

Fluconazole is well absorbed after oral administration (> 90% bioavailability), and serum levels approach those seen after administering the same dose intravenously. Thus, unless the patient cannot take medication by mouth or is hemodynamically unstable, the preferred route of administration is by mouth. While generally well tolerated, fluconazole is associated with dose-dependent nausea and vomiting. Altered liver function tests (alanine aminotransferase [ALT], aspartate aminotransferase [AST]) and hepatitis have been reported. While less potent than other azoles (itraconazole, voriconazole), fluconazole inhibits cytochrome P450 resulting in reduced elimination of certain agents. Rifampin and phenytoin increase metabolism of fluconazole necessitating increased fluconazole dosage.

Itraconazole is an oral triazole with variable bioavailability. It is moderately well absorbed from the gastrointestinal tract (food increases absorption from 30% to 60%; antacids and H_2-receptor antagonists decrease absorption) and widely distributed in tissues with the notable exception of the central nervous system, where levels in spinal fluid are undetectable. Itraconazole solution is more predictably absorbed than the tablets. While the tablet formulation should be administered with food, the solution is best absorbed on an empty stomach. The drug is metabolized by the liver, and no dosage adjustment is needed in kidney disease. Itraconazole is very active against most strains of *Histoplasma capsulatum, Blastomyces dermatitidis, Cryptococcus neoformans, Sporotrichum schenkii*, and various dermatophytes. It is also active against *Aspergillus* species but inactive against *Fusarium* and *Zygomycetes.* Itraconazole in doses of 200–400 mg/d is effective and approved therapy for localized or disseminated histoplasmosis. It is also effective in sporotrichosis, dermatophytic infections (including those of the nails), and oral and esophageal candidiasis. Itraconazole is at least as effective as fluconazole in the treatment of nonmeningeal coccidioidomycosis and may be superior in the management of skeletal disease. At doses of 200 mg twice daily, itraconazole increases exercise tolerance and decreases corticosteroid requirements in patients with allergic bronchopulmonary aspergillosis. Itraconazole has been approved for onychomycosis. Pulse therapy with 200 mg twice daily for 1 week each month, repeated for 4 consecutive months, is effective in 70% of cases.

Adverse effects are similar to those of fluconazole, with anorexia, nausea, vomiting, and abdominal pain occurring most commonly. Skin rash has been reported in up to 8% of patients. Hepatitis and hypokalemia occur uncommonly. Exacerbation of heart failure occasionally occurs with itraconazole. Drugs that increase hepatic drug-metabolizing enzymes (isoniazid, rifampin, phenytoin, phenobarbital) may increase itraconazole metabolism, and increased doses may be needed when these drugs are administered concurrently with itraconazole. Itraconazole also impairs the metabolism of cyclosporine and can result in increased levels of certain agents, including digoxin and warfarin.

The usual dosage is 200 mg once or twice daily with meals.

Voriconazole is a triazole antifungal with broad in vitro activity against most species of *Candida* and molds, *Aspergillus*, *Fusarium*, *Pseudallescheria*, and others. It is as efficacious as liposomal amphotericin in the therapy of documented and suspected fungal infections in febrile neutropenic patients, and it is superior to liposomal amphotericin in preventing breakthrough fungemias. Voriconazole is superior to conventional amphotericin in the treatment of disseminated aspergillosis. Animal data also suggest voriconazole to be the most effective agent against *Aspergillus*, particularly in combination with caspofungin or another echinocandin. Voriconazole is the drug of choice in the treatment of *Fusarium* and *Scedosporium* infections. Voriconazole is widely used in the treatment of neutropenic patients with suspected or documented fungal infection. Voriconazole has limited activity against zygomycete pathogens, and some centers have reported increased rates of infection due to *Rhizopus* and *Mucor* in stem cell transplantation patients receiving voriconazole. Similar to fluconazole, oral administration leads to predictable absorption. The primary toxicity associated with voriconazole is infusion-related, transient visual disturbances, particularly during the first week of therapy. In addition, voriconazole is associated with photosensitivity reactions. Similar to itraconazole, voriconazole is associated with hepatotoxicity and numerous drug interactions. Enzyme inducers can decrease voriconazole plasma levels with possible reduction in efficacy. Voriconazole inhibits cytochrome P450 activity reducing the clearance of numerous agents, including cyclosporine and tacrolimus.

Posaconazole is an antifungal derivative of itraconazole with similar spectrum of activity as voriconazole, including yeast and *Aspergillus* spp. Unique from voriconazole, posaconazole has activity against the zygomycete fungi approaching that of amphotericin. Salvage treatment studies demonstrate efficacy in the treatment of these pathogens. Posaconazole is superior to fluconazole as prophylaxis of neutropenia. The drug is only available as an oral formulation, which may limit its use in more acutely ill patients. Posaconazole should always be administered with food to ensure adequate oral bioavailability; the drug is primarily eliminated via nonrenal mechanisms. Similar to the other azole agents, posaconazole has primarily upper gastrointestinal adverse events and occasional liver function test abnormalities. While not as problematic as voriconazole, posaconazole is an inhibitor of cytochrome P450.

Ketoconazole , the first orally bioavailable azole, previously was used in the treatment of a variety of fungal infections. However, the improved spectrum of activity, reduced toxicity, and superior pharmacokinetics of newer azoles have reduced ketoconazole to a secondary role.

Echinocandins

The echinocandins (anidulafungin, caspofungin, micafungin) act by inhibiting fungal cell wall synthesis. They are active against *Candida,* including nonalbicans species, as well as *Aspergillus* species. They are not active against *Cryptococcus* or *Fusarium.* Their long pharmacologic half-life confers the advantage of once-daily dosing. No change in dose is necessary in patients with kidney disease; however, moderate to severe hepatic disease necessitates a reduction in dosage for caspofungin. Because rifampin and phenytoin significantly increase the metabolism of caspofungin, increased doses of the antifungal are necessary when rifampin and phenytoin are given concomitantly. Animal data suggest that caspofungin is inferior to voriconazole in the treatment of *Aspergillus;* however, the addition of caspofungin to voriconazole has been associated with in vitro and in vivo additive or synergistic effects. Caspofungin is superior to conventional amphotericin B in the treatment of candidemia, primarily on the basis of greater patient tolerability. The echinocandins should be considered the drugs of choice in the treatment of infections due to *C glabrata* and *C krusei.* Micafungin has been found to be as effective and less toxic than liposomal amphotericin in the treatment of candidemia and invasive candidiasis. Anidulafungin is at least as effective as fluconazole in the treatment of invasive candidiasis. These agents are associated with minimal toxicity or adverse effects. Histamine release is common with basic polypeptide compounds, such as the echinocandins; thus infusion-related reactions have been reported. While increased liver function tests have been observed with the combination of caspofungin and cyclosporine, more recent analyses suggest that these two agents can be safely administered together. Considering the similarities in spectrum efficacy and safety between products, the choice of echinocandin likely will be based on cost differences.

Antiviral Chemotherapy

Several compounds can influence viral replication and the development of viral disease.

Amantadine is active against influenza A (but not influenza B) and previously has been effective both as prophylaxis and therapy. However, more recently, the high rate of influenza resistance has resulted in amantadine (and rimantadine) no longer recommended in the treatment of influenza. Yearly immunization against influenza is the primary intervention for disease prevention. The usual adult dosage is 200 mg orally per day (in persons over 65 years of age, 100 mg). Worldwide rates of amantadine/rimantadine resistance have significantly increased over the years. Considering this predisposition for resistance, neuraminidase inhibitors such as zanamivir or oseltamivir are the drugs of choice for both treatment and prophylaxis. In preparation for a possible avian influenza pandemic, the CDC recommends the neuraminidase inhibitors due to current resistance trends and documented past record of development of amantadine resistance while on therapy. The most marked untoward effects of amantadine include insomnia, nightmares, and ataxia, especially in the elderly. Amantadine may accumulate and be more toxic in patients with kidney disease, and the dosage should be reduced. **Rimantadine**, an analog of amantadine, is as effective as amantadine and is associated with fewer central nervous system adverse effects. **Rimantadine is recommended by the CDC preferentially over amantidine in the treatment of influenza.**

Neuraminidase inhibitors, including zanamivir inhalation and oseltamivir tablets, are available for prevention and treatment of influenza A and B and are also active against the avian influenza virus. However, the 2008-09 influenza season has been associated with widespread oseltamavir resistance in the predominant influenza A strain, H1N1; these isolates have remained uniformly susceptible to zanamivir. Oseltamivir-resistant isolates of avian influenza virus also are often susceptible to zanamivir. While no vaccine for avian influenza is currently available, future prevention will depend on immunization rather than on antivirals. As with amantadine and rimantadine, the neuraminidase inhibitors must be administered soon (within 48 hours) after the onset of symptoms to be effective. Zanamivir inhalers are difficult to use for some patients, especially those with asthma and chronic obstructive pulmonary disease, in whom bronchospasm has been reported. Gastrointestinal adverse events are the most commonly observed side effects with oseltamivir. Both drugs are administered twice daily (oseltamavir, 75 mg orally; zanamivir 10 mg inhalation) for 5 days when used for therapy. Both agents reduce the duration of symptoms by only 1 day and viral shedding by 2 days. Both agents also effectively prevent disease in household contacts when administered prophylactically (oseltamavir 75 mg orally once daily, zanamavir 10 mg inhaled once daily) for 10 days.

Acyclovir is active against herpes simplex virus and varicella-zoster virus. In herpes-infected cells, it is selectively active against viral DNA polymerase and thus inhibits virus proliferation. Given intravenously (15 mg/kg/d in three divided doses), it is useful in the treatment of mucocutaneous herpes simplex in immunocompromised patients. It can reduce pain, accelerate healing, and prevent dissemination of herpes zoster and varicella in immunocompromised patients. The usual dosage for serious varicella-zoster infections is 30 mg/kg/d intravenously in three equal doses. The drug has no effect on establishment of latency, frequency of recurrence, or incidence of postherpetic neuralgia. Acyclovir (30 mg/kg/d intravenously in three equal doses) is the drug of choice for herpes encephalitis. Intravenous or oral acyclovir is effective prophylaxis against recurrent mucocutaneous and visceral herpes infections in transplant and other severely immunosuppressed patients. Prophylactic intravenous or oral acyclovir is effective in preventing cytomegalovirus (CMV) disease in some transplant settings (renal and perhaps bone marrow) but not in others (liver).

Oral acyclovir, 400 mg three times daily for 7–10 days, is effective in primary genital herpes simplex infections. Oral acyclovir at a dose of 800 mg three times a day for 2 days for recurrent genital herpes reduces viral shedding and symptoms. Suppressive therapy (400 mg twice daily) for 4–6 months reduces the frequency and severity of recurrent genital herpetic lesions. Acyclovir minimally affects symptoms or viral shedding in recurrent herpes labialis and is not generally used for this disease. However, in a dose of 400 mg twice daily, it is effective in preventing recurrent herpes labialis in those with frequent relapses and in preventing sun-induced relapses.

Other uses of oral acyclovir include (1) therapy of acute herpetic keratitis and prevention of recurrences, (2) prevention and treatment of herpetic whitlow, (3) acceleration of healing of herpes zoster in immunocompetent patients if initiated within 48 hours after onset (800 mg five times daily for 7 days), (4) more rapid healing of rash and lessened clinical symptoms of primary varicella in adults and children if instituted within 24 hours after onset of rash and continued for 5–7 days, (5) therapy of herpes proctitis (400 mg five times daily for 10 days), (6) prevention of herpes simplex and CMV infections in transplant recipients (in doses of 800 mg four or five times daily), (7) prevention of erythema multiforme that is herpes simplex–related, and (8) prophylaxis against varicella in susceptible household contacts.

Topical 5% acyclovir ointment can shorten the period of pain and viral shedding in herpes simplex mucocutaneous oral lesions in immunosuppressed patients but not in patients with normal immunity. In contrast, acyclovir cream or penciclovir ointment (see famciclovir, below) appears to reduce the duration of pain and viral shedding by approximately 1 day in immunocompetent patients. Oral acyclovir is significantly more efficacious than topical therapy.

The absolute oral bioavailability of acyclovir is 10–30%. Famciclovir and valacyclovir (see below) are significantly better absorbed than oral acyclovir and are administered less frequently. Dosage reduction in kidney disease is required. Since hemodialysis reduces serum levels significantly, the daily dose should be given after hemodialysis.

Acyclovir is relatively nontoxic. Precipitation of drug in renal tubules has been described with intravenous acyclovir and can best be avoided by maintaining adequate hydration and urine flow. Central nervous system toxicity manifested by confusion, agitation, tremors, and hallucinations has been reported. Resistance has been described, usually in immunosuppressed patients who have received multiple courses of therapy.

Famciclovir is a prodrug of penciclovir. After oral administration, 75–80% is absorbed and deacetylated in the intestinal wall to the active drug, penciclovir. Penciclovir, like acyclovir, inhibits viral replication by interfering with viral DNA polymerase. Acyclovir-resistant strains of herpes simplex and varicella-zoster virus are also resistant to famciclovir. Famciclovir in a dose of 500 mg three times daily for 7 days accelerates healing of lesions in acute herpes zoster if started within 72 hours after the onset of rash. At a dose of 125 mg twice daily for 5 days, famciclovir is effective therapy of recurrent genital herpes; at a dose of 500 mg twice daily, it is effective as chronic suppressive therapy.

Valacyclovir is a prodrug of acyclovir that has significantly increased oral bioavailability when compared with acyclovir. After absorption, it is converted to acyclovir and serum levels are three to five times higher than those achieved with acyclovir. Valacyclovir at a dosage of 1 g three times daily for 7–10 days is effective therapy for herpes zoster when started within 72 hours after onset of rash and is slightly more effective than acyclovir in relieving zoster-associated pain. It shortens the course of initial episodes of genital herpes (1 g twice daily for 7–10 days), can be used to treat recurrent genital herpes (500 mg twice daily for three days), and is effective prophylaxis for recurrent genital herpes when given as a single 1-g daily dose. Valacyclovir prophylaxis (500 mg daily) reduces the rate of viral shedding and transmission of herpes in discordant monogamous couples. At doses of 2 g four times daily, valacyclovir is more effective than placebo in preventing CMV infections in seronegative recipients of a kidney from a seropositive donor. The adverse effect profile of valacyclovir is comparable to that of acyclovir.

Foscarnet (trisodium phosphonoformate) is a pyrophosphate analog that inhibits viral DNA polymerase of human herpesviruses (CMV, herpes simplex, varicella-zoster) and the reverse transcriptase of HIV. The drug is less well tolerated than acyclovir and ganciclovir and more difficult to administer. Therefore, its use is limited to patients who do not respond to ganciclovir or acyclovir or cannot tolerate these drugs. Isolates of CMV resistant to ganciclovir and herpes simplex and varicella-zoster isolates resistant to acyclovir usually are susceptible to foscarnet. Foscarnet has been used to treat acyclovir-resistant mucocutaneous herpes simplex in AIDS patients as well as varicella cutaneous lesions in AIDS patients who did not respond to acyclovir. Oral absorption is poor, and the drug must be given intravenously. The half-life is 3–5 hours, and this is prolonged with kidney disease. The usual induction dose is 60 mg/kg/dose every 8 hours, and the dose for maintenance therapy is 120 mg/kg once daily. Adjustments are required for even minimal impairment in kidney function (see package insert).

Foscarnet can cause severe phlebitis and generally necessitates central intravenous access unless substantially diluted. Nephrotoxicity, which is dose-dependent and reversible, is its major toxicity. Prehydration with 2.5 L of 0.9% saline reduces nephrotoxicity. Foscarnet binds divalent cations, and hypocalcemia peripheral neuropathy, seizures and arrhythmias, hypomagnesemia, and hypophosphatemia can occur. Monitoring of electrolytes and kidney function is required during therapy. Anemia (20–50%) and nausea and vomiting (20–30%) are other common adverse effects.

Cidofovir is a nucleotide analog that is active against most all human herpesviruses and poxviruses. The drug has a prolonged pharmacokinetic intracellular half-life, allowing for administration every 1–2 weeks. Strains of CMV, herpes simplex virus, and herpes zoster virus that are resistant to ganciclovir or acyclovir often are susceptible to cidofovir. However, the least likely cross-resistance is between foscarnet and cidofovir. Cidofovir delays progression of CMV retinitis in newly diagnosed disease (5 mg/kg weekly for 2 weeks, followed by maintenance of 3–5 mg/kg every other week) and is effective therapy in relapsed disease or in patients who are intolerant of traditional therapy (5 mg/kg every other day). The drug is ineffective or only marginally effective in the treatment of AIDS-associated progressive multifocal leukoencephalopathy.

Cidofovir is associated with a high incidence of nephrotoxicity, sometimes severe. To avoid this complication, probenecid and intravenous saline are administered with each dose. Ocular toxicity, including uveitis and iritis, is another complication reported with cidofovir.

Ribavirin aerosol is used in the treatment of respiratory syncytial virus infections in bone marrow transplant patients. It is not known whether the addition of immune globulin provides additional benefit. Intravenous ribavirin (compassionate use availability only) can significantly lower the fatality rate of Lassa fever and has been used as a therapeutic agent for hantavirus pneumonia. However, the benefit in hantavirus infection is unclear. While used in some patients in the treatment of severe acute respiratory syndrome (SARS), its value and tolerability has been debated. During the SARS outbreak in Toronto, the use of high-dose ribavirin was associated with a high rate of anemia, hypomagnesemia, and bradycardia. The drug is teratogenic in animals, and pregnant women should not take care of patients receiving the aerosol. Oral ribavirin is used in combination with interferons to treat chronic hepatitis C infections (see Chapter 16: Liver, Biliary Tract, & Pancreas Disorders). The combination has been found to be superior to monotherapy with interferon.

Ganciclovir is an analog of acyclovir that has broad antiviral activity, including activity against CMV. The drug is efficacious in the therapy of CMV retinitis in AIDS patients, but once therapy is stopped, the relapse rate is high, unless the patient is receiving highly active antiretroviral therapy (HAART). Ganciclovir resistance has decreased from the high levels observed in the pre-HAART era, probably due to improved antiretroviral therapy. It has been suggested that the addition of intravenous immunoglobulin or CMV immune globulin to ganciclovir may improve outcomes associated with CMV pneumonitis. Ganciclovir is frequently used in solid organ and stem cell transplant patients in the treatment and prevention of infection. However, there is no uniformity of opinion about the duration of therapy or the route of administration. Before the availability of oral valganciclovir (see below), which results in serum levels equivalent to those achieved with intravenous drug, ganciclovir was frequently administered intravenously and in the immediate posttransplant period for 1–2 weeks. Depending on the type of transplant (bone marrow transplant patients are at greater risk for developing CMV disease than solid organ transplant patients) and the serologic status of the donor and recipient (seronegative recipients who receive transplants from seropositive donors are at greatest risk for developing disease), various antiviral agents were used to prevent infection. Acyclovir, valacyclovir, ganciclovir, and valganciclovir have been used in the prevention of CMV in stem cell transplant patients. With the availability of oral valganciclovir, many transplant patients—especially those with the greatest risk of developing CMV infection—are placed on this drug as prophylaxis. In addition, because tests to detect early infection with CMV are very sensitive, the strategy for prevention has shifted from one of universal prophylaxis to one of preemptive therapy. At many institutions, high-risk patients are routinely screened for CMV DNA in blood by antigen detection or polymerase chain reaction. A positive test results in subsequent preemptive therapy with intravenous ganciclovir or oral valganciclovir.

The major adverse effect is neutropenia, which is reversible but may require the concomitant use of colony stimulating factors. Thrombocytopenia, nausea, rash, and phlebitis occur less commonly.

Oral ganciclovir is rarely used because of its poor bioavailability, and it has been replaced by **valganciclovir**, an esterification product of ganciclovir that is significantly better absorbed. Administration of 900 mg of valganciclovir orally results in serum ganciclovir levels equal to that achieved with an intravenous 5 mg/kg dose of ganciclovir. In CMV retinitis in AIDS patients, the drug is as efficacious as intravenous therapy. Valganciclovir is widely used as prophylaxis in transplant patients; however, it is inferior to oral ganciclovir in the prevention of CMV infection after liver transplant. Consequently, it has not been approved for that indication.

Lamivudine (3TC), a well-tolerated oral antiviral nucleoside analog used in treatment of HIV infection, is effective against hepatitis B. Once-daily therapy (100 mg) results in clinical, serologic, and histologic improvement in approximately 50% of patients. While lamivudine is useful, development of resistance is common with long-term therapy. Therapy post–liver transplantation is associated with a reduced risk of reinfection with hepatitis B. Unlike the combination of ribavirin and interferon, lamivudine does not improve the outcome seen with interferon monotherapy.

Adefovir is an antiviral agent with activity against hepatitis B. It is as effective against lamivudine-susceptible and lamivudine-resistant isolates. While previously used higher doses have been associated with substantial nephrotoxicity, this complication is rare with the lower doses (10 mg/d) used to treat hepatitis B. Twenty-five to 35 percent of patients experience marked increases in liver function tests associated with discontinuation of adefovir, presumably secondary to rebound viral replication. The drug is primarily eliminated by the kidney.

Entecavir is a nucleoside analog drug that has selective antihepatitis B virus (HBV) activity against both lamivudine-susceptible and lamivudine-resistant isolates. For patients with chronic hepatitis B who are beginning treatment for the first time (nucleoside-naïve patients), the recommended dosage of entecavir is a single 0.5-mg tablet taken once daily on an empty stomach; for those patients infected with lamivudine-resistant isolates, a single 1-mg tablet is taken once daily. While entecavir is useful for lamivudine-resistant isolates, cross-resistance has been observed among HBV nucleoside analogs. In cell-based assays, entecavir had 8- to 30-fold less inhibition of replication of HBV that contained lamivudine-resistant mutations than of wild-type virus. Adverse events are similar to those of other hepatitis B agents and include severe, acute exacerbation of hepatitis B after discontinuation as well as headache, abdominal pain, diarrhea, fatigue, and dizziness.

Telbivudine, the most recently approved agent, is also active against both lamivudine-susceptible and lamivudine-resistant isolates and comparative trials demonstrate clear superiority over lamivudine. The advantages over lamivudine include both viral suppression as well as normalization of ALT. Combination therapy with telbivudine and lamivudine does not offer any advantages over monotherapy with telbivudine. It is well absorbed by the oral route and food has no impact upon bioavailability. Telbivudine is administered once daily and patients with moderate to severe kidney disease require dosage adjustment. The adverse effect profile is comparable to that observed with other nucleoside analogs.

Human interferons have been prepared from stimulated lymphocytes and by DNA recombinant technology. These agents have antiviral, antitumor, and immunoregulatory properties. The most common uses of these agents include therapy of chronic hepatitis due to hepatitis B, C, and D (see Chapter 16: Liver, Biliary Tract, & Pancreas Disorders). A long-acting preparation of interferon, peginterferon, in combination with oral ribavirin is superior to conventional interferon for therapy of hepatitis C. Relapse of the underlying disease after cessation of therapy is common but usually responds to reinstitution of drug. Adverse effects are common and include an influenza-like illness with fever, chills, nausea, vomiting, headache, arthralgia, and myalgias. Bone marrow suppression, especially with high-dose therapy, also occurs. Considering the poor tolerability of interferon, only a minority of patients infected with hepatitis C are actually candidates for therapy.

Essentials of Diagnosis

- Risk factors: sexual contact with an infected person, parenteral exposure to infected blood by transfusion or needle sharing, perinatal exposure.
- Prominent systemic complaints such as sweats, diarrhea, weight loss, and wasting.
- Opportunistic infections due to diminished cellular immunity—often life-threatening.
- Aggressive cancers, particularly Kaposi sarcoma and extranodal lymphoma.
- Neurologic manifestations, including dementia, aseptic meningitis, and neuropathy.

General Considerations

When AIDS was first recognized in the United States in 1981, cases were identified by finding severe opportunistic infections such as *Pneumocystis* pneumonia that indicated profound defects in cellular immunity in the absence of other causes of immunodeficiency. When the syndrome was found to be caused by HIV, it became obvious that severe opportunistic infections and unusual neoplasms were at one end of a spectrum of disease, while healthy seropositive individuals were at the other end.

The Centers for Disease Control and Prevention (CDC) AIDS case definition (Table 31–1) includes opportunistic infections and malignancies that rarely occur in the absence of severe immunodeficiency (eg, *Pneumocystis* pneumonia, central nervous system lymphoma). It also classifies persons as having AIDS if they have positive HIV serology and certain infections and malignancies that can occur in immunocompetent hosts but that are more common among persons infected with HIV (pulmonary tuberculosis, invasive cervical cancer). Several nonspecific conditions, including dementia and wasting (documented weight loss)—in the presence of a positive HIV serology—are considered AIDS. The definition includes criteria for both definitive and presumptive diagnoses of certain infections and malignancies. Finally, persons with positive HIV serology who have ever had a CD4 lymphocyte count below 200 cells/mcL or a CD4 lymphocyte percentage below 14% are considered to have AIDS. Inclusion of persons with low CD4 counts as AIDS cases reflects the recognition that immunodeficiency is the defining characteristic of AIDS. The choice of a cutoff point at 200 cells/mcL is supported by several cohort studies showing that AIDS will develop within 3 years in over 80% of persons with counts below this level in the absence of effective antiretroviral therapy (ART). The 1993 definition was also expanded to include persons with positive HIV serology and pulmonary tuberculosis (Plate 66), recurrent pneumonia, and invasive cervical cancer. The prognosis of persons with HIV/AIDS has dramatically improved due to the introduction of highly active antiretroviral therapy (HAART) in the mid 1990s. One consequence is that fewer persons with HIV ever develop an infection or malignancy or have a low enough CD4 count to classify them as having AIDS, which means that the CDC definition has become a less useful measure of the impact of HIV/AIDS in the United States. Conversely, persons in whom AIDS had been diagnosed based on a serious opportunistic infection, malignancy, or immunodeficiency may now be markedly healthier, with high CD4 counts, due to the use of HAART. Therefore, the Social Security Administration as well as most social service agencies focus on functional assessment for determining eligibility for benefits rather than the simple presence or absence of an AIDS-defined illness.

Table 31–1. CDC AIDS case definition for surveillance of adults and adolescents.

Definitive AIDS diagnoses (with or without laboratory evidence of HIV infection)
1. Candidiasis of the esophagus, trachea, bronchi, or lungs.
2. Cryptococcosis, extrapulmonary.
3. Cryptosporidiosis with diarrhea persisting > 1 month.
4. Cytomegalovirus disease of an organ other than liver, spleen, or lymph nodes.
5. Herpes simplex virus infection causing a mucocutaneous ulcer that persists longer than 1 month; or bronchitis, pneumonitis, or esophagitis of any duration.
6. Kaposi sarcoma in a patient < 60 years of age.
7. Lymphoma of the brain (primary) in a patient < 60 years of age.
8. *Mycobacterium avium* complex or *Mycobacterium kansasii* disease, disseminated (at a site other than or in addition to lungs, skin, or cervical or hilar lymph nodes).
9. *Pneumocystis jiroveci* pneumonia.
10. Progressive multifocal leukoencephalopathy.
11. Toxoplasmosis of the brain.
Definitive AIDS diagnoses (with laboratory evidence of HIV infection)

1. Coccidioidomycosis, disseminated (at a site other than or in addition to lungs or cervical or hilar lymph nodes).
2. HIV encephalopathy.
3. Histoplasmosis, disseminated (at a site other than or in addition to lungs or cervical or hilar lymph nodes).
4. Isosporiasis with diarrhea persisting > 1 month.
5. Kaposi sarcoma at any age.
6. Lymphoma of the brain (primary) at any age.
7. Other non-Hodgkin lymphoma of B cell or unknown immunologic phenotype.
8. Any mycobacterial disease caused by mycobacteria other than *Mycobacterium tuberculosis*, disseminated (at a site other than or in addition to lungs, skin, or cervical or hilar lymph nodes).
9. Disease caused by extrapulmonary *M tuberculosis.*
10. *Salmonella* (nontyphoid) septicemia, recurrent.
11. HIV wasting syndrome.
12. CD4 lymphocyte count below 200 cells/mcL or a CD4 lymphocyte percentage below 14%.
13. Pulmonary tuberculosis.
14. Recurrent pneumonia.
15. Invasive cervical cancer.
Presumptive AIDS diagnoses (with laboratory

evidence of HIV infection)
1. Candidiasis of esophagus: (a) recent onset of retrosternal pain on swallowing; and (b) oral candidiasis.
2. Cytomegalovirus retinitis. A characteristic appearance on serial ophthalmoscopic examinations.
3. Mycobacteriosis. Specimen from stool or normally sterile body fluids or tissue from a site other than lungs, skin, or cervical or hilar lymph nodes, showing acid-fast bacilli of a species not identified by culture.
4. Kaposi sarcoma. Erythematous or violaceous plaque-like lesion on skin or mucous membrane.
5. *Pneumocystis jiroveci* pneumonia: (a) a history of dyspnea on exertion or nonproductive cough of recent onset (within the past 3 months); and (b) chest x-ray evidence of diffuse bilateral interstitial infiltrates or gallium scan evidence of diffuse bilateral pulmonary disease; and (c) arterial blood gas analysis showing an arterial oxygen partial pressure of < 70 mm Hg or a low respiratory diffusing capacity of < 80% of predicted values or an increase in the alveolar-arterial oxygen tension gradient; and (d) no evidence of a bacterial pneumonia.
6. Toxoplasmosis of the brain: (a) recent onset of a focal neurologic abnormality consistent with intracranial disease or a reduced level of consciousness; and (b) brain imaging evidence of a lesion having a mass effect or the

radiographic appearance of which is enhanced by injection of contrast medium; and (c) serum antibody to toxoplasmosis or successful response to therapy for toxoplasmosis.
7. Recurrent pneumonia: (a) more than one episode in a 1-year period; and (b) acute pneumonia (new symptoms, signs, or radiologic evidence not present earlier) diagnosed on clinical or radiologic grounds by the patient's physician.
8. Pulmonary tuberculosis: (a) apical or miliary infiltrates and (b) radiographic and clinical response to antituberculous therapy.
Plate 66
Advanced bilateral pulmonary tuberculosis. (Public Health Image Library, CDC.)

Epidemiology

The modes of transmission of HIV are similar to those of hepatitis B, in particular with respect to sexual, parenteral, and vertical transmission. Although certain sexual practices (eg, receptive anal intercourse) are significantly riskier than other sexual practices (eg, oral sex), it is difficult to quantify per-contact risks. The reason is that studies of sexual transmission of HIV show that most people at risk for HIV infection engage in a variety of sexual practices and have sex with multiple persons, only some of whom may actually be HIV infected. Thus, it is difficult to determine which practice with which person actually resulted in HIV transmission.

Nonetheless, the best available estimates indicate that the risk of HIV transmission with receptive anal intercourse is between 1:100 and 1:30, with insertive anal intercourse 1:1000, with receptive vaginal intercourse 1:1000, with insertive vaginal intercourse 1:10,000, and with receptive fellatio with ejaculation 1:1000. The per-contact risk of HIV transmission with other behaviors, including receptive fellatio without ejaculation, insertive fellatio, and cunnilingus, is not known.

All per-contact risk estimates assume that the source is HIV infected. If the HIV status of the source is unknown, the risk of transmission is the risk of transmission multiplied by the probability that the source is HIV infected. This would vary by risk practices, age, and geographic area. A number of cofactors are known to increase the risk of HIV transmission during a given encounter, including the presence of ulcerative or inflammatory sexually transmitted diseases, trauma, menses, and lack of male circumcision.

The risk of acquiring HIV infection from a needlestick with infected blood is approximately 1:300. Factors known to increase the risk of transmission include depth of penetration, hollow bore needles, visible blood on the needle, and advanced stage of disease in the source. The risk of HIV transmission from a mucosal splash with infected blood is unknown but is assumed to be significantly lower.

The risk of acquiring HIV infection from illicit drug use with sharing of needles from an HIV-infected source is estimated to be 1:150. Use of clean needles markedly decreases the chance of HIV transmission but does not eliminate it if other drug paraphernalia are shared (eg, cookers).

When blood transfusion from an HIV-infected donor occurs, the risk of transmission is 95%. Fortunately, since 1985, blood donor screening using the HIV enzyme-linked immunosorbent assay (ELISA) has been universally practiced in the United States. Also, persons who have recently engaged in unsafe behaviors (eg, sex with a person at risk for HIV, injection drug use) are not allowed to donate. This eliminates donations from persons who are HIV infected but have not yet developed antibodies (ie, persons in the "window" period). In recent years, HIV antigen and viral load testing have been added to the screening of blood to further lower the chance of HIV transmission. With these precautions, the chance of HIV transmission with receipt of blood transfusion is about 1:1,000,000.

In the absence of perinatal HIV prophylaxis, between 13% and 40% of children born to HIV-infected mothers contract HIV infection. The risk is higher with vaginal than with cesarean delivery, higher among mothers with high viral loads, and higher among those who breast-feed their children. The risk can be decreased by administering antiretroviral treatment to the mother during pregnancy and to the infant immediately after birth (see below).

HIV has not been shown to be transmitted by respiratory droplet spread, by vectors such as mosquitoes, or by casual nonsexual contact.

Current estimates are that about 950,000 Americans are infected with HIV, and there are about 53,000 new infections each year. At the end of 2006, there were an estimated 448,871 persons in the United States living with AIDS. Of those, 76% are men, of whom 60% were exposed through male-to-male sexual contact, 19% were exposed through injection drug use, 12% were exposed through heterosexual contact, and 8% were exposed through male-to-male sexual contact and injection drug use. Women account for 23% of living persons, of whom 66% were infected through heterosexual contact and 32% were exposed through injection drug use. Children account for less than 1% of living cases. African Americans have been disproportionately hard hit by the epidemic. The estimated rate in 2006 of new AIDS cases in the United States per 100,000 population was 60.3 among African Americans, 20.8 among Latinos, 7.8 among native Americans and native Alaskans, 6.4 among whites, and 4.4 among Asians and Pacific Islanders.

In general, the progression of HIV-related illness is similar in men and women. However, there are some important differences. Women are at risk for gynecologic complications of HIV, including recurrent candidal vaginitis, pelvic inflammatory disease, and cervical dysplasia. Violence directed against women, pregnancy, and frequent occurrence of drug use and poverty all complicate the treatment of HIV-infected women. Although "safer sex" campaigns dramatically decreased the rates of seroconversions among men who have sex with men (MSM) living in metropolitan areas in the United States by the mid 1980s, relapse to unsafe sexual practices among MSM in several large cities in the United States and in western Europe has been observed. The higher rates of unsafe sex appear to be related to decreased concern about acquiring HIV due to the availability of HAART. Decreased interest in following safer sex recommendations and increasing use of crystal methamphetamine among certain risk groups also appears to be playing a role in the increased unsafe sex rates.

Worldwide there are an estimated 33 million persons infected with HIV. In Central and East Africa in some urban areas, as many as one-third of sexually active adults are infected. HIV infection began to spread in Asia in the late 1980s. The most common mode of transmission is bidirectional heterosexual spread. The reason for the greater risk for transmission with heterosexual intercourse in Africa and Asia than in the United States may relate to cofactors such as general health status, the presence of genital ulcers, relative lack of male circumcision, the number of sexual partners, and different HIV serotypes.

Etiology

HIV, like other retroviruses, depends on a unique enzyme, reverse transcriptase (RNA-dependent DNA polymerase), to replicate within host cells. The other major pathogenic human retrovirus, human T cell lymphotropic/leukemia virus (HTLV)-I, is associated with lymphoma, while HIV is not known to be directly oncogenic. The HIV genomes contain genes for three basic structural proteins and at least five other regulatory proteins; *gag* codes for group antigen proteins, *pol* codes for polymerase, and *env* codes for the external envelope protein. The greatest variability in strains of HIV occurs in the viral envelope. Since neutralizing activity is found in antibodies directed against the envelope, this variability presents problems for vaccine development.

In addition to the classic AIDS virus (HIV-1), a group of related viruses, HIV-2, has been isolated in West African patients. HIV-2 has the same genetic organization as HIV-1, but there are significant differences in the envelope glycoproteins. Some infected individuals exhibit AIDS-like illnesses, but the rate of progression in individuals infected with HIV-2 appears to be slower than that of HIV-1 infection. HIV-2 remains relatively rare in the United States but has become more common in Western Europe due to immigration from endemic areas. Cases have been documented in which AIDS-like illnesses have occurred in the absence of HIV infection or other known infectious causes of immunodeficiency.

Pathogenesis

The hallmark of symptomatic HIV infection is immunodeficiency caused by continuing viral replication. The virus can infect all cells expressing the T4 (CD4) antigen, which HIV uses to attach to the cell. Chemokine co-receptors (CCR5 and CXCR4) are required for virus entry, and individuals with CCR5 deletions are less likely to become infected and, once infected, the disease is more likely to progress slowly. Once it enters a cell, HIV can replicate and cause cell fusion or death. A latent state is also established, with integration of the HIV genome into the cell's genome. The cell principally infected is the CD4 (helper-inducer) lymphocyte, which directs many other cells in the immune network. With increasing duration of infection, the number of CD4 lymphocytes falls. Some of the immunologic defects, however, are explained not by *quantitative* abnormalities of lymphocyte subsets but by *qualitative* defects in CD4 responsiveness induced by HIV.

Other cells in the immune network that are infected by HIV include B lymphocytes and macrophages. The defect in B cells is partly due to disordered CD4 lymphocyte function. These direct and indirect effects can lead to generalized hypergammaglobulinemia and can also depress B cell responses to new antigen challenges. Because of these defects, the immunodeficiency of HIV is mixed. Elements of humoral and cellular immunodeficiency are present, especially in children.

Macrophages act as a reservoir for HIV and serve to disseminate it to other organ systems (eg, the central nervous system).

Apart from the immunologic effects of HIV, the virus can also directly cause a variety of neurologic effects. Neuropathology largely results from the release of cytokines and other neurotoxins by infected macrophages. Perturbations of excitatory neurotransmitters and calcium flux may contribute to neurologic dysfunction. Direct HIV infection of renal tubular cells and gastrointestinal epithelium may contribute to these organ system manifestations of infection.

Pathophysiology

Clinically, the syndromes caused by HIV infection are usually explicable by one of three known mechanisms: immunodeficiency, autoimmunity, and allergic and hypersensitivity reactions.

Immunodeficiency

Immunodeficiency is a direct result of the effects of HIV upon immune cells. A spectrum of infections and neoplasms is seen, as in other congenital or acquired immunodeficiency states. Two remarkable features of HIV immunodeficiency are the low incidence of certain infections such as listeriosis and aspergillosis and the frequent occurrence of certain neoplasms such as lymphoma or Kaposi sarcoma. This latter complication has been seen primarily in MSM or in bisexual men, and its incidence has steadily declined through the first 15 years of the epidemic. A herpesvirus (KSHV or HHV-8) is the cause of Kaposi sarcoma.

Autoimmunity/Allergic & Hypersensitivity Reactions

Autoimmunity can occur as a result of disordered cellular immune function or B lymphocyte dysfunction. Examples of both lymphocytic infiltration of organs (eg, lymphocytic interstitial pneumonitis) and autoantibody production (eg, immunologic thrombocytopenia) occur. These phenomena may be the only clinically apparent disease or may coexist with obvious immunodeficiency. Moreover, HIV-infected individuals appear to have higher rates of allergic reactions to unknown allergens as seen with eosinophilic pustular folliculitis ("itchy red bump syndrome") as well as increased rates of hypersensitivity reactions to medications (for example, the fever and sunburn-like rash seen with trimethoprim-sulfamethoxazole reactions).

Clinical Findings

The complications of HIV-related infections and neoplasms affect virtually every organ. The general approach to the HIV-infected person with symptoms is to evaluate the organ systems involved, aiming to diagnose treatable conditions rapidly. As can be seen in Figure 31–

1, the CD4 lymphocyte count provides very important prognostic information. Certain infections may occur at any CD4 count, while others rarely occur unless the CD4 lymphocyte count has dropped below a certain level. For example, a patient with a CD4 count of 600 cells/mcL, cough, and fever may have a bacterial pneumonia but would be very unlikely to have *Pneumocystis* pneumonia.

Figure 31–1

Relationship of CD4 count to development of opportunistic infections. MAC, *Mycobacterium avium* complex; CMV, cytomegalovirus; CNS, central nervous system.

Symptoms and Signs

Many individuals with HIV infection remain asymptomatic for years even without antiretroviral therapy, with a mean time of approximately 10 years between exposure and development of AIDS. When symptoms occur, they may be remarkably protean and nonspecific. Since virtually all the findings may be seen with other diseases, a combination of complaints is more suggestive of HIV infection than any one symptom.

Physical examination may be entirely normal. Abnormal findings range from completely nonspecific to highly specific for HIV infection. Those that are specific for HIV infection include hairy leukoplakia of the tongue, disseminated Kaposi sarcoma, and cutaneous bacillary angiomatosis. Generalized lymphadenopathy is common early in infection.

Systemic complaints

Fever, night sweats, and weight loss are common symptoms in HIV-infected patients and may occur without a complicating opportunistic infection. Patients with persistent **fever** and no localizing symptoms should nonetheless be carefully examined, and evaluated with a chest radiograph (*Pneumocystis* pneumonia can present without respiratory symptoms), bacterial blood cultures if the fever is greater than 38.5 °C, serum cryptococcal antigen, and mycobacterial cultures of the blood. Sinus CT scans or sinus radiographs should be considered to evaluate occult sinusitis. If these studies are normal, patients should be observed closely. Antipyretics are useful to prevent dehydration.

Weight loss is a particularly distressing complication of long-standing HIV infection. Patients typically have disproportionate loss of muscle mass, with maintenance or less substantial loss of fat stores. The mechanism of HIV-related weight loss is not completely understood but appears to be multifactorial.

AIDS patients frequently suffer from anorexia, nausea, and vomiting, all of which contribute to weight loss by decreasing caloric intake. In some cases, these symptoms are secondary to a specific infection, such as viral hepatitis. In other cases, however, evaluation of the symptoms yields no specific pathogen, and it is assumed to be due to a primary effect of HIV. Malabsorption also plays a role in decreased caloric intake. Patients may suffer diarrhea from infections with bacterial, viral, or parasitic agents.

Exacerbating the decrease in caloric intake, many AIDS patients have an increased metabolic rate. This increased rate has been shown to exist even among asymptomatic HIV-infected persons, but it accelerates with disease progression and secondary infection. AIDS patients with secondary infections also have decreased protein synthesis, which makes maintaining muscle mass difficult.

Several strategies have been developed to slow AIDS wasting. Effective fever control decreases the metabolic rate and may slow the pace of weight loss, as does treating the underlying opportunistic infection. Food supplementation with high-calorie drinks may enable patients with not much appetite to maintain their intake. Selected patients with otherwise good functional status and weight loss due to unrelenting nausea, vomiting, or diarrhea may benefit from total parenteral nutrition (TPN). It should be noted, however, that TPN is more likely to increase fat stores than to reverse the muscle wasting process.

Two pharmacologic approaches for increasing appetite and weight gain are the progestational agent megestrol acetate (80 mg four times a day) and the antiemetic agent dronabinol (2.5–5 mg three times a day). Side effects from megestrol acetate are rare, but thromboembolic phenomena, edema, nausea, vomiting, and rash have been reported. Euphoria, dizziness, paranoia, and somnolence and even nausea and vomiting have been reported in 3–10% of patients using dronabinol. Dronabinol contains only one of the active ingredients in smoked marijuana, and many patients report better relief of nausea and improvement of appetite with smoking marijuana. Several states allow physicians to recommend the use of smoked marijuana to their patients. However, it is still illegal in the United States to sell marijuana. Thus, a physician's recommendation may at best decrease the chance that patients will be prosecuted for use of marijuana. Unfortunately, neither megestrol acetate nor dronabinol increases lean body mass.

Two regimens that have resulted in increases in lean body mass are growth hormone and anabolic steroids. Growth hormone at a dose of 0.1 mg/kg/d (up to 6 mg) subcutaneously for 12 weeks has resulted in modest increases in lean body mass. Treatment with growth hormone can cost as much as $10,000 per month. Anabolic steroids also increase lean body mass among HIV-infected patients. They seem to work best for patients who are able to do weight training. The most commonly used regimens are testosterone enanthate or testosterone cypionate (100– 200 mg intramuscularly every 2–4 weeks). Testosterone transdermal system (apply 5 mg system each evening) and testosterone gel (1%; apply a 5-g packet [50 mg testosterone] to clean, dry skin daily) are also available. The anabolic steroid oxandrolone (20 mg orally in two divided doses) has also been found to increase lean body mass.

Nausea leading to weight loss is sometimes due to esophageal candidiasis. Patients with oral candidiasis and nausea should be empirically treated with an oral antifungal agent. Patients with weight loss due to nausea of unclear origin may benefit from use of antiemetics prior to meals (prochlorperazine, 10 mg three times daily; metoclopramide, 10 mg three times daily; or ondansetron, 8 mg three times daily). Dronabinol (5 mg three times daily) can also be used to increase appetite. Depression and adrenal insufficiency are two potentially treatable causes of weight loss.

Pulmonary disease

Pneumocystis pneumonia

(See also discussions in Chapter 36: Mycotic Infections.) *Pneumocystis jiroveci* pneumonia is the most common opportunistic infection associated with AIDS. *Pneumocystis* pneumonia may be difficult to diagnose because the symptoms—fever, cough, and shortness of breath—are nonspecific. Furthermore, the severity of symptoms ranges from fever and no respiratory symptoms through mild cough or dyspnea to frank respiratory distress.

Hypoxemia may be severe, with a PO_2 less than 60 mm Hg. The cornerstone of diagnosis is the chest radiograph. Diffuse or perihilar infiltrates are most characteristic, but only two-thirds of patients with *Pneumocystis* pneumonia have this finding. Normal chest radiographs are seen in 5–10% of patients with *Pneumocystis* pneumonia, while the remainder have atypical infiltrates. Apical infiltrates are commonly seen among patients with *Pneumocystis* pneumonia who have been receiving aerosolized pentamidine prophylaxis. Large pleural effusions are uncommon with *Pneumocystis* pneumonia; their presence suggests bacterial pneumonia, other infections such as tuberculosis, or pleural Kaposi sarcoma.

Definitive diagnosis can be obtained in 50–80% of cases by Wright-Giemsa stain or direct fluorescence antibody (DFA) test of induced sputum. Sputum induction is performed by having patients inhale an aerosolized solution of 3% saline produced by an ultrasonic nebulizer. Patients should not eat for at least 8 hours and should not use toothpaste or mouthwash prior to the procedure since they can interfere with test interpretation. The next step for patients with negative sputum examinations in whom *Pneumocystis* pneumonia is still suspected should be bronchoalveolar lavage. This technique establishes the diagnosis in over 95% of cases.

In patients with symptoms suggestive of *Pneumocystis* pneumonia but with negative or atypical chest radiographs and negative sputum examinations, other diagnostic tests may provide additional information in deciding whether to proceed to bronchoalveolar lavage. Elevation of serum lactate dehydrogenase occurs in 95% of cases of *Pneumocystis* pneumonia, but the specificity of this finding is at best 75%. Either a normal diffusing capacity of carbon monoxide (DLCO) or a high-resolution CT scan of the chest that demonstrates no interstitial lung disease makes the diagnosis of *Pneumocystis* pneumonia very unlikely. In addition, a CD4 count above 250 cells/mcL within 2 months prior to evaluation of respiratory symptoms makes a diagnosis of *Pneumocystis* pneumonia unlikely; only 1–5% of cases occur above this CD4 count level (Figure 31–1: illustration). This is true even if the patient previously had a CD4 count lower than 200 cells/mcL but has had an increase with antiretroviral therapy. Pneumothoraces can be seen in HIV-infected patients with a history of *Pneumocystis* pneumonia, especially if they have received aerosolized pentamidine treatment.

Other infectious pulmonary diseases

Other infectious causes of pulmonary disease in AIDS patients include bacterial, mycobacterial, and viral pneumonias. Community-acquired pneumonia is the most common cause of pulmonary disease in HIV-infected persons. An increased incidence of pneumococcal pneumonia with septicemia and *Haemophilus influenzae* pneumonia has been reported. *Pseudomonas aeruginosa* is an important respiratory pathogen in advanced disease. The incidence of infection with *Mycobacterium tuberculosis* has markedly increased in metropolitan areas because of HIV infection as well as homelessness. Tuberculosis occurs in an estimated 4% of persons in the United States who have AIDS. Apical infiltrates and disseminated disease occur more commonly than among immunocompetent persons. Although a purified protein derivative (PPD) test should be performed on all HIV-infected persons in whom a diagnosis of tuberculosis is being considered, the lower the CD4 cell count, the greater the likelihood of anergy. Because "anergy" skin test panels do not accurately classify those patients who are infected with tuberculosis but unreactive to the PPD, they are not recommended. Treatment of HIV-infected persons with active tuberculosis is similar to treatment of HIV-uninfected tubercular individuals. However, rifampin should not be given to patients receiving indinavir, nelfinavir, amprenavir, lopinavir, or delavirdine. In these cases, rifabutin may be substituted, but it may require dosing modifications depending on the antiretroviral regimen. Multidrug-resistant tuberculosis is a major problem in several metropolitan areas. Noncompliance with prescribed antituberculous drugs is a major risk factor. Several of the reported outbreaks appear to implicate nosocomial spread. The emergence of drug resistance makes it essential that antibiotic sensitivities be performed on all positive cultures. Drug therapy should be individualized. Patients with multidrug-resistant *M tuberculosis* infection should receive at least three drugs to which their organism is sensitive. Atypical mycobacteria can cause pulmonary disease in AIDS patients with or without preexisting lung disease and responds variably to treatment. Making a distinction between *M tuberculosis* and atypical mycobacteria requires culture of sputum specimens. If culture of the sputum produces acid-fast bacilli, definitive identification may take several weeks using traditional techniques. DNA probes allow for presumptive identification usually within days of a positive culture. While awaiting definitive diagnosis, clinicians should err on the side of treating patients as if they have *M tuberculosis* infection.

In cases in which the risk of atypical mycobacteria is very high (eg, a person without risk for tuberculosis exposure with a CD4 count under 50 cells/mcL—see Figure 31–1: illustration), clinicians may wait for definitive diagnosis if the person is smear-negative for acid-fast bacilli, clinically stable, and not living in a communal setting. Isolation of cytomegalovirus from bronchoalveolar lavage fluid occurs commonly in AIDS patients but does not establish a definitive diagnosis. Diagnosis of CMV pneumonia requires biopsy; response to treatment is poor. Histoplasmosis, coccidioidomycosis, and cryptococcal disease should also be considered in the differential diagnosis of unexplained pulmonary infiltrates.

Noninfectious pulmonary diseases

Noninfectious causes of lung disease include Kaposi sarcoma, non-Hodgkin lymphoma, and interstitial pneumonitis. In patients with known Kaposi sarcoma, pulmonary involvement complicates the course in approximately one-third of cases. However, pulmonary involvement is rarely the presenting manifestation of Kaposi sarcoma. Non-Hodgkin lymphoma may involve the lung as the sole site of disease but more commonly involves other organs as well, especially the brain, liver, and gastrointestinal tract. Both of these processes may show nodular or diffuse parenchymal involvement, pleural effusions, and mediastinal adenopathy on chest radiographs.

Nonspecific interstitial pneumonitis may mimic *Pneumocystis* pneumonia. Lymphocytic interstitial pneumonitis seen in lung biopsies has a variable clinical course. Typically, these patients present with several months of mild cough and dyspnea; chest radiographs show interstitial infiltrates. Many patients with this entity undergo transbronchial biopsies in an attempt to diagnose *Pneumocystis* pneumonia. Instead, the tissue shows interstitial inflammation ranging from an intense lymphocytic infiltration (consistent with lymphoid interstitial pneumonitis) to a mild mononuclear inflammation. Corticosteroids may be helpful in some cases refractory to antiretroviral therapy.

Sinusitis

Chronic sinusitis can be a frustrating problem for HIV-infected patients even in those on adequate antiretroviral therapy. Symptoms include sinus congestion and discharge, headache, and fever. Some patients may have radiographic evidence of sinus disease on sinus CT scan or sinus x-ray in the absence of significant symptoms. Nonsmoking patients with purulent drainage should be treated with amoxicillin (500 mg orally three times a day). Patients who smoke should be treated with amoxicillin-potassium clavulanate (500 mg orally three times a day) to cover *H influenzae.* Prolonged treatment (3–6 weeks) with an antibiotic and guaifenesin (600 mg orally twice daily) to decrease sinus congestion may be required. For patients not responding to amoxicillin-potassium clavulanate, levofloxacin should be tried (400 mg orally daily). Some patients may require referral to an otolaryngologist for sinus drainage.

Central Nervous System Disease

Central nervous system disease in HIV-infected patients can be divided into intracerebral space-occupying lesions, encephalopathy, meningitis, and spinal cord processes. Many of these complications have declined markedly in prevalence in the era of HAART.

Toxoplasmosis

Toxoplasmosis is the most common space-occupying lesion in HIV-infected patients. Headache, focal neurologic deficits, seizures, or altered mental status may be presenting symptoms. The diagnosis is usually made presumptively based on the characteristic appearance of cerebral imaging studies in an individual known to be seropositive for *Toxoplasma*. Typically, toxoplasmosis appears as multiple contrast-enhancing lesions on CT scan. Lesions tend to be peripheral, with a predilection for the basal ganglia.

Single lesions are atypical of toxoplasmosis. When a single lesion has been detected by CT scanning, MRI scanning may reveal multiple lesions because of its greater sensitivity. If a patient has a single lesion on MRI and is neurologically stable, clinicians may pursue a 2-week empiric trial of toxoplasmosis therapy. A repeat scan should be performed at 2 weeks. If the lesion has not diminished in size, biopsy of the lesion should be performed. Since many HIV-infected patients will have detectable titers, a positive *Toxoplasma* serologic test does not confirm the diagnosis. Conversely, less than 3% of patients with toxoplasmosis have negative titers. Therefore, negative *Toxoplasma* titers in an HIV-infected patient with a space-occupying lesion should be a cause for aggressively pursuing an alternative diagnosis.

Central nervous system lymphoma

Primary non-Hodgkin lymphoma is the second most common space-occupying lesion in HIV-infected patients. Symptoms are similar to those with toxoplasmosis. While imaging techniques cannot distinguish these two diseases with certainty, lymphoma more often is solitary. Other less common lesions should be suspected if there is preceding bacteremia, positive tuberculin test, fungemia, or injection drug use. These include bacterial abscesses, cryptococcomas, tuberculomas, and *Nocardia* lesions.

Because techniques for stereotactic brain biopsy have improved, this procedure plays an increasing role in diagnosing cerebral lesions. Biopsy should be strongly considered if lesions are solitary or do not respond to toxoplasmosis treatment, especially if they are easily accessible. Diagnosis of lymphoma is important because many patients benefit from treatment (radiation therapy). In the future, it may be possible to avoid brain biopsy by utilizing polymerase chain reaction (PCR) assay of cerebrospinal fluid for Epstein-Barr virus DNA, which is present in 90% of CNS lymphoma cases.

AIDS dementia complex

The diagnosis of AIDS dementia complex (HIV-associated cognitive-motor complex) is one of exclusion based on a brain imaging study and on spinal fluid analysis that excludes other pathogens. Neuropsychiatric testing is helpful in distinguishing patients with dementia from those with depression. Patients with AIDS dementia complex typically have difficulty with cognitive tasks and exhibit diminished motor speed. Patients may first notice a deterioration in their handwriting. The manifestations of dementia may wax and wane, with persons exhibiting periods of lucidity and confusion over the course of a day. Many patients improve with effective antiretroviral treatment. Metabolic abnormalities may also cause changes in mental status: hypoglycemia, hyponatremia, hypoxia, and drug overdose are important considerations in this population. Other less common infectious causes of encephalopathy include progressive multifocal leukoencephalopathy (discussed below), CMV, syphilis, and herpes simplex encephalitis.

Cryptococcal meningitis

Cryptococcal meningitis typically presents with fever and headache. Less than 20% of patients have meningismus. Diagnosis is based on a positive latex agglutination test that detects cryptococcal (or "CRAG") or positive culture of spinal fluid for *Cryptococcus*. Seventy to 90% of patients with cryptococcal meningitis have a positive serum CRAG. Thus, a negative serum CRAG test makes a diagnosis of cryptococcal meningitis unlikely and can be useful in the initial evaluation of a patient with headache, fever, and normal mental status. HIV meningitis, characterized by lymphocytic pleocytosis of the spinal fluid with negative culture, is common early in HIV infection.

HIV myelopathy

Spinal cord function may also be impaired in HIV-infected individuals. HIV myelopathy presents with leg weakness and incontinence. Spastic paraparesis and sensory ataxia are seen on neurologic examination. Myelopathy is usually a late manifestation of HIV disease, and most patients will have concomitant HIV encephalopathy. Pathologic evaluation of the spinal cord reveals vacuolation of white matter. Because HIV myelopathy is a diagnosis of exclusion, symptoms suggestive of myelopathy should be evaluated by lumbar puncture to rule out CMV polyradiculopathy (described below) and an MRI or CT scan to exclude epidural lymphoma.

Progressive multifocal leukoencephalopathy (PML)

PML is a viral infection of the white matter of the brain seen in patients with very advanced HIV infection. It typically results in focal neurologic deficits such as aphasia, hemiparesis, and cortical blindness. Imaging studies are strongly suggestive of the diagnosis if they show nonenhancing white matter lesions without mass effect. Extensive lesions may be difficult to differentiate from the changes caused by HIV. Several patients have stabilized or improved after the institution of combination antiretroviral therapy or cidofovir.

Peripheral Nervous System

Peripheral nervous system syndromes include inflammatory polyneuropathies, sensory neuropathies, and mononeuropathies.

An inflammatory demyelinating polyneuropathy similar to Guillain-Barré syndrome occurs in HIV-infected patients, usually prior to frank immunodeficiency. The syndrome in many cases improves with plasmapheresis, supporting an autoimmune basis of the disease. CMV can cause an ascending polyradiculopathy characterized by lower extremity weakness and a neutrophilic pleocytosis on spinal fluid analysis with a negative bacterial culture. Transverse myelitis can be seen with herpes zoster or CMV.

Peripheral neuropathy is common among HIV-infected persons. Patients typically complain of numbness, tingling, and pain in the lower extremities. Symptoms are disproportionate to findings on gross sensory and motor evaluation. Beyond HIV infection itself, the most common cause is prior antiretroviral therapy with stavudine or didanosine. Patients who report these symptoms should be switched to an alternative agent if possible. Caution should be used when administering these agents to patients with a history of peripheral neuropathy. Unfortunately, drug-induced neuropathy is not always reversed when the offending agent is discontinued. Patients with advanced disease may also develop peripheral neuropathy even if they have never taken antiretroviral therapy. Evaluation should rule out other causes of sensory neuropathy such as alcoholism, thyroid disease, vitamin B12 deficiency, and syphilis.

Treatment of peripheral neuropathy is aimed at symptomatic relief. Patients should be initially treated with gabapentin (start at 300 mg at bedtime and increase to 300–900 mg orally three times a day).

Rheumatologic Manifestations

Arthritis, involving single or multiple joints, with or without effusion, has been commonly noted in HIV-infected patients. Involvement of large joints is most common. Although the cause of HIV-related arthritis is unknown, most patients will respond to nonsteroidal anti-inflammatory drugs. Patients with a sizable effusion, especially if the joint is warm or erythematous, should have the joint tapped, followed by culture of the fluid to rule out suppurative arthritis as well as fungal and mycobacterial disease.

Several rheumatologic syndromes, including reactive arthritis (Reiter syndrome), psoriatic arthritis, sicca syndrome, and systemic lupus erythematosus, have been reported in HIV-infected patients (see Chapter 19: Musculoskeletal & Immunologic Disorders). However, it is unclear if the prevalence is greater than in the general population. Cases of avascular necrosis of the femoral heads have been reported sporadically, generally in the setting of advanced disease with long-standing infection and in patients receiving long-term antiretroviral therapy. The etiology is not clear but is probably multifactorial in nature.

Myopathy

Myopathies are infrequent in the era of effective antiretroviral therapy but can be related to either HIV-infection or antiretroviral therapy, particularly with use of zidovudine (azidothymidine [AZT]). Proximal muscle weakness is typical, and patients may have varying degrees of muscle tenderness. A muscle biopsy can distinguish HIV myopathy from zidovudine myopathy and should be considered in patients for whom continuation of zidovudine is essential.

Retinitis

Complaints of visual changes must be evaluated immediately in HIV-infected patients. CMV retinitis, characterized by perivascular hemorrhages and white fluffy exudates, is the most common retinal infection in AIDS patients and can be rapidly progressive. In contrast, cotton wool spots, which are also common in HIV-infected people, are benign, remit spontaneously, and appear as small indistinct white spots without exudation or hemorrhage. This distinction may be difficult at times for the nonspecialist, and patients with visual changes should be seen by an ophthalmologist. Other rare retinal processes include other herpesvirus infections or toxoplasmosis.

Oral Lesions

The presence of oral candidiasis or hairy leukoplakia is significant for several reasons. First, these lesions are highly suggestive of HIV infection in patients who have no other obvious cause of immunodeficiency. Second, several studies have indicated that patients with candidiasis have a high rate of progression to AIDS even with statistical adjustment for CD4 count.

Hairy leukoplakia is caused by the Epstein-Barr virus. The lesion is not usually troubling to patients and sometimes regresses spontaneously. Hairy leukoplakia is commonly seen as a white lesion on the lateral aspect of the tongue. It may be flat or slightly raised, is usually corrugated, and has vertical parallel lines with fine or thick ("hairy") projections. Oral candidiasis can be bothersome to patients, many of whom report an unpleasant taste or mouth dryness. There are two major types of oral candidiasis: pseudomembranous (removable white plaques) and erythematous (red friable plaques). Treatment is with topical agents such as clotrimazole 10-mg troches (one troche four or five times a day). Patients with candidiasis who do not respond to topical antifungals can be treated with fluconazole (50–100 mg orally once a day for 3–7 days). Chronic suppression of oral candidiasis with fluconazole has been associated with development of candidiasis resistant to all available azoles and thus should be avoided except in frequently recurring cases.

Angular cheilitis—fissures at the sides of the mouth—is usually due to *Candida* as well and can be treated topically with ketoconazole cream (2%) twice a day.

Gingival disease is common in HIV-infected patients and is thought to be due to an overgrowth of microorganisms. It usually responds to professional dental cleaning and chlorhexidine rinses. A particularly aggressive gingivitis or periodontitis will develop in some HIV-infected patients; these patients should be given antibiotics that cover anaerobic oral flora (eg, metronidazole, 250 mg four times a day for 4 or 5 days) and referred to oral surgeons with experience with these entities.

Aphthous ulcers are painful and may interfere with eating. They can be treated with fluocinonide (0.05% ointment mixed 1:1 with plain Orabase and applied six times a day to the ulcer). For lesions that are difficult to reach, patients should use dexamethasone swishes (0.5 mg in 5 mL elixir three times a day). The pain of the ulcers can be relieved with use of an anesthetic spray (10%lidocaine). For patients with refractory ulcers, thalidomide, starting at a dose of 50 mg orally daily and increasing to 100–200 mg daily, has proved useful. Because it is teratogenic, it should be administered only to patients at zero risk of procreation. The most common side effects are sedation and peripheral neuropathy. Other lesions seen in the mouths of HIV-infected patients include Kaposi sarcoma (usually on the hard palate) and warts.

Gastrointestinal Manifestations

Candidal esophagitis

(See also discussion in Chapter 15: Gastrointestinal Disorders.) Esophageal candidiasis is a common AIDS complication. In a patient with characteristic symptoms, empiric antifungal treatment is begun with fluconazole (200 mg daily for 10–14 days). Further evaluation to identify other causes of esophagitis (herpes simplex, CMV) is reserved for patients who do not improve with antifungal treatment.

Hepatic disease

Autopsy studies have demonstrated that the liver is a frequent site of infections and neoplasms in HIV-infected patients. However, many of these infections are not clinically symptomatic. Clinicians may note elevations of alkaline phosphatase and aminotransferases on routine chemistry panels. Mycobacterial disease, CMV, hepatitis B virus, hepatitis C virus, and lymphoma cause liver disease and can present with varying degrees of nausea, vomiting, right upper quadrant abdominal pain, and jaundice. Sulfonamides, imidazole drugs, antituberculous medications, pentamidine, clarithromycin, and didanosine have also been associated with hepatitis. HIV-infected patients with chronic hepatitis may have more rapid progression of liver disease because of the concomitant immunodeficiency or hepatotoxicity of antiretroviral therapy. Percutaneous liver biopsy may be helpful in diagnosing liver disease, but some common causes of liver disease (eg, *Mycobacterium avium* complex, lymphoma) can be determined by less invasive measures (eg, blood culture, biopsy of a more accessible site). With patients living longer as a result of advances in antiretroviral therapy, advanced liver disease and hepatic failure due to chronic active hepatitis B and or C are increasing causes of morbidity and mortality. HIV-infected individuals who are coinfected with hepatitis B, should be treated with antiretroviral regimens that include drugs with activity against both viruses (eg, lamivudine [3TC], emtricitabine [FTC], tenofovir [TDF]). Treatment of HIV-infected persons with hepatitis C with peginterferon and ribavirin has been shown to be efficacious, although less so than in HIV-uninfected persons. HIV-infected persons are also more likely to have difficulty tolerating treatment with peginterferon than uninfected persons. Liver transplants have been performed successfully in HIV-infected patients. This strategy is most likely to be successful in persons who have CD4 counts above 100 cells/mcL and nondetectable viral loads.

Biliary disease

Cholecystitis presents with manifestations similar to those seen in immunocompetent hosts but is more likely to be acalculous. Sclerosing cholangitis and papillary stenosis have also been increasingly reported in HIV-infected patients. Typically, the syndrome presents with severe nausea, vomiting, and right upper quadrant pain. Liver function tests generally show alkaline phosphatase elevations disproportionate to elevation of the aminotransferases. Although dilated ducts can be seen on ultrasound, the diagnosis is made by endoscopic retrograde cholangiopancreatography, which reveals intraluminal irregularities of the proximal intrahepatic ducts with "pruning" of the terminal ductal branches. Stenosis of the distal common bile duct at the papilla is commonly seen with this syndrome. CMV, *Cryptosporidium*, and microsporidia are thought to play inciting roles in this syndrome.

Enterocolitis

Enterocolitis is a common problem in HIV-infected individuals. Organisms known to cause enterocolitis include bacteria (*Campylobacter*, *Salmonella*, *Shigella*), viruses (CMV, adenovirus), and protozoans (*Cryptosporidium*, *Entamoeba histolytica*, *Giardia*, *Isospora*, microsporidia). HIV itself may cause enterocolitis. Several of the organisms causing enterocolitis in HIV-infected individuals also cause diarrhea in immunocompetent persons. However, HIV-infected patients tend to have more severe and more chronic symptoms, including high fevers and severe abdominal pain that can mimic acute abdominal catastrophes. Bacteremia and concomitant biliary involvement are also more common with enterocolitis in HIV-infected patients. Relapses of enterocolitis following adequate therapy have been reported with both *Salmonella* and *Shigella* infections.

Because of the wide range of agents known to cause enterocolitis, a stool culture and multiple stool examinations for ova and parasites (including modified acid-fast staining for *Cryptosporidium*) should be performed. Those patients who have *Cryptosporidium* in one stool with improvement in symptoms in less than 1 month should not be considered to have AIDS, as *Cryptosporidium* is a cause of self-limited diarrhea in HIV-negative persons. More commonly, HIV-infected patients with *Cryptosporidium* infection have persistent enterocolitis with profuse watery diarrhea.

To date, no consistently effective treatments have been developed for *Cryptosporidium* infection. The most effective treatment of cryptosporidiosis is to improve immune function through the use of effective antiretroviral treatment. The diarrhea can be treated symptomatically with diphenoxylate with atropine (one or two tablets orally three or four times a day). Those who do not respond may be given paregoric with bismuth (5–10 mL orally three or four times a day). Octreotide in escalating doses (starting at 0.05 mg subcutaneously every 8 hours for 48 hours) has been found to ameliorate symptoms in approximately 40% of patients with cryptosporidia or idiopathic HIV-associated diarrhea.

Patients with a negative stool examination and persistent symptoms should be evaluated with colonoscopy and biopsy. Patients whose symptoms last longer than 1 month with no identified cause of diarrhea are considered to have a presumptive diagnosis of AIDS enteropathy. Patients may respond to institution of effective antiretroviral treatment. Upper endoscopy with small bowel biopsy is not recommended as a routine part of the evaluation.

Other disorders

Two other important gastrointestinal abnormalities in HIV-infected patients are gastropathy and malabsorption. It has been documented that some HIV-infected patients do not produce normal levels of stomach acid and therefore are unable to absorb drugs that require an acid medium. This decreased acid production may explain, in part, the susceptibility of HIV-infected patients to *Campylobacter*, *Salmonella*, and *Shigella*, all of which are sensitive to acid concentration. There is no evidence that *Helicobacter pylori* is more common in HIV-infected persons.

A malabsorption syndrome occurs commonly in HIV-infected patients. It can be due to infection of the small bowel with *M avium* complex, *Cryptosporidium*, or microsporidia.

Endocrinologic Manifestations

Hypogonadism is probably the most common endocrinologic abnormality in HIV-infected men. The adrenal gland is also a commonly afflicted endocrine gland in patients with AIDS. Abnormalities demonstrated on autopsy include infection (especially with CMV and *M avium* complex), infiltration with Kaposi sarcoma, and injury from hemorrhage and presumed autoimmunity. The prevalence of clinically significant adrenal insufficiency is low. Patients with suggestive symptoms should undergo a cosyntropin stimulation test.

Although frank deficiency of cortisol is rare, an isolated defect in mineralocorticoid metabolism may lead to salt-wasting and hyperkalemia. Such patients should be treated with fludrocortisone (0.1–0.2 mg daily).

AIDS patients appear to have abnormalities of thyroid function tests different from those of patients with other chronic diseases. AIDS patients have been shown to have high levels of triiodothyronine (T_3), thyroxine (T4), and thyroid-binding globulin and low levels of reverse triiodothyronine (rT_3). The causes and clinical significance of these abnormalities are unknown.

Skin Manifestations

The skin manifestations that commonly develop in HIV-infected patients can be grouped into viral, bacterial, fungal, neoplastic, and nonspecific dermatitides.

Herpes simplex infections occur more frequently, tend to be more severe, and are more likely to disseminate in AIDS patients than in immunocompetent persons. Because of the risk of progressive local disease, all herpes simplex attacks should be treated with acyclovir (400 mg orally three times a day until healed, usually 7 days), famciclovir (500 mg orally twice daily until healed), or valacyclovir (500 mg orally twice daily until healed). To avoid the complications of attacks, many clinicians recommend suppressive therapy for HIV-infected patients with a history of recurrent herpes. Options for suppressive therapy include acyclovir (400 mg orally twice daily), famciclovir (250 mg orally twice daily), and valacyclovir (500 mg orally daily). A randomized trial of women infected with both herpes simplex and HIV showed that suppressive therapy with valacyclovir at a dose of 500 mg orally twice daily decreased genital and plasma HIV-1 RNA levels, suggesting the possibility that suppressive treatment may reduce HIV transmission.

Herpes zoster is a common manifestation of HIV infection. As with herpes simplex infections, patients with zoster should be treated with acyclovir to prevent dissemination (800 mg orally four or five times per day for 7 days). Alternatively, famciclovir (500 mg orally three times a day) or valacyclovir (500 mg three times a day) may be used. Vesicular lesions should be cultured if there is any question about their origin, since herpes simplex responds to much lower doses of acyclovir. Disseminated zoster and cases with ocular involvement should be treated with intravenous (10 mg/kg every 8 hours for 7–10 days) rather than oral acyclovir.

Molluscum contagiosum caused by a pox virus is seen in HIV-infected patients, as in other immunocompromised patients. The characteristic umbilicated fleshy papular lesions have a propensity for spreading widely over the patient's face and neck and should be treated with topical liquid nitrogen.

Staphylococcus is the most common bacterial cause of skin disease in HIV-infected patients; it usually presents as **folliculitis, superficial abscesses (furuncles)** , or **bullous impetigo.** Because dissemination with sepsis has been reported, attempts should be made to treat these lesions aggressively. Folliculitis is initially treated with topical clindamycin or mupirocin, and patients may benefit from regular washing with an antibacterial soap such as chlorhexidine. Intranasal mupirocin has been used successfully for staphylococcal decolonization in other settings. In HIV-infected patients with recurrent staphylococcal infections, weekly intranasal mupirocin should be considered in addition to topical care and systemic antibiotics. Abscesses often require incision and drainage. Patients may need antistaphylococcal antibiotics as well. Due to high frequency of methicillin-resistant *Staphylococcus aureus* (MRSA) skin infections in HIV-infected populations, lesions should be cultured prior to initiating empiric antistaphylococcal therapy. Although there is limited experience treating MRSA with oral antibiotics, current recommendations for empiric treatment are trimethoprim-sulfamethoxazole (one double-strength tablet orally twice daily) or doxycycline (100 mg orally twice daily) with close follow-up.

Bacillary angiomatosis is a well-described entity in HIV-infected patients. It is caused by two closely related organisms: *Bartonella henselae* and *Bartonella quintana*. The epidemiology of these infections suggests zoonotic transmission from fleas of infected domestic cats. The most common manifestation is raised, reddish, highly vascular skin lesions that can mimic the lesions of Kaposi sarcoma. Fever is a common manifestation of this infection; involvement of bone, lymph nodes, and liver has also been reported. The infection responds to doxycycline, 100 mg orally twice daily, or erythromycin, 250 mg orally four times daily. Therapy is continued for at least 14 days, and patients who are seriously ill with visceral involvement may require months of therapy.

The majority of **fungal rashes** afflicting AIDS patients are due to dermatophytes and *Candida*. These are particularly common in the inguinal region but may occur anywhere on the body. Fungal rashes generally respond well to topical clotrimazole (1% twice a day) or ketoconazole (2% twice a day).

Seborrheic dermatitis is more common in HIV-infected patients. Scrapings of seborrhea have revealed *Malassezia furfur (Pityrosporum ovale)*, implying that the seborrhea is caused by this fungus. Consistent with the isolation of this fungus is the clinical finding that seborrhea responds well to topical clotrimazole (1% cream) as well as hydrocortisone (1% cream).

Xerosis presents in HIV-infected patients with severe pruritus. The patient may have no rash, or nonspecific excoriations from scratching. Treatment is with emollients (eg, absorption base cream) and antipruritic lotions (eg, camphor 9.5% and menthol 0.5%).

Psoriasis can be very severe in HIV-infected patients. Phototherapy and etretinate (0.25–9.75 mg/kg/d orally in divided doses) may be used for recalcitrant cases in consultation with a dermatologist. Because of the underlying immunodeficiency, methotrexate should be avoided.

HIV-Related Malignancies

Four cancers are currently included in the CDC classification of AIDS: Kaposi sarcoma, non-Hodgkin lymphoma, primary lymphoma of the brain, and invasive cervical carcinoma. Epidemiologic studies have shown that between 1973 and 1987 among single men in San Francisco, the risk of Kaposi sarcoma increased more than 5000-fold and the risk of non-Hodgkin lymphoma more than tenfold. The increase in incidence of malignancies is probably a function of impaired cell-mediated immunity.

Kaposi sarcoma lesions may appear anywhere; careful examination of the eyelids, conjunctiva, pinnae, palate, and toe webs is mandatory to locate potentially occult lesions. In light-skinned individuals, Kaposi lesions usually appear as purplish, nonblanching lesions that can be papular or nodular (Plate 41). In dark-skinned individuals, the lesions may appear more brown. In the mouth, lesions are most often palatal papules, though exophytic lesions of the tongue and gingivae may also be seen. Kaposi lesions may be confused with other vascular lesions such as angiomas and pyogenic granulomas. Visceral disease (eg, gastrointestinal, pulmonary) will develop in about 40% of patients with dermatologic Kaposi sarcoma. Rapidly progressive dermatologic or visceral disease is best treated with systemic chemotherapy. Liposomally encapsulated doxorubicin given intravenously every 3 weeks has a response rate of approximately 70%. -Interferon (10 million units subcutaneously three times a week) also has activity against Kaposi sarcoma. However, symptoms such as malaise and anorexia limit the utility of this therapy. Patients with milder forms of Kaposi sarcoma do not require specific treatment as the lesions usually improve and can completely resolve with antiretroviral therapy. However, it should be noted that the lesions may flare when antiretroviral therapy is first initiated—probably as a result of an immune reconstitution process (see Inflammatory reactions below).

Plate 41

Cutaneous nodule of Kaposi sarcoma in AIDS. (Courtesy of Dr. Steve Kraus, Public Health Image Library, CDC.)

Non-Hodgkin lymphoma in HIV-infected persons tends to be very aggressive. The malignancies are usually of B cell origin and characterized as diffuse large-cell tumors. Over 70% of the malignancies are extranodal.

The prognosis of patients with systemic non-Hodgkin lymphoma depends primarily on the degree of immunodeficiency at the time of diagnosis. Patients with high CD4 counts do markedly better than those diagnosed at a late stage of illness. Patients with primary central nervous system lymphoma are treated with radiation. Response to treatment is good, but prior to the availability of HAART, most patients died within a few months after diagnosis due to their underlying disease. Systemic disease is treated with chemotherapy. Common regimens are CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisone) and modified M-BACOD (methotrexate, bleomycin, doxorubicin, cyclophosphamide, vincristine, and dexamethasone). Granulocyte colony-stimulating factor (G-CSF; filgrastim) is used to maintain white blood counts with this latter regimen. Intrathecal chemotherapy is administered to prevent or treat meningeal involvement.

Although **Hodgkin disease** is not included as part of the CDC definition of AIDS, studies have found that HIV infection is associated with a fivefold increase in the incidence of Hodgkin disease. HIV-infected persons with Hodgkin disease are more likely to have mixed cellularity and lymphocyte depletion subtypes of Hodgkin disease and to seek medical attention at an advanced stage of disease.

Anal dysplasia and squamous cell carcinoma have been noted in HIV-infected men and women. These lesions have been strongly correlated with previous infection by human papillomavirus (HPV). Although many of the infected MSM report a history of anal warts or have visible warts, a significant percentage have silent papillomavirus infection. Cytologic (using Papanicolaou smears) and papillomavirus DNA studies can easily be performed on specimens obtained by anal swab. Because of the risk of progression from dysplasia to cancer in immunocompromised patients, some experts suggest that annual anal swabs for cytologic examination should be done in all HIV-infected persons. An anal Papanicolaou smear is performed by rotating a moistened Dacron swab about 2 cm into the anal canal. The swab is immediately inserted into a cytology bottle.

HPV also appears to play a causative role in **cervical dysplasia and neoplasia.** The incidence and clinical course of cervical disease in HIV-infected women are discussed below.

Gynecologic Manifestations

Vaginal candidiasis, cervical dysplasia and neoplasia, and pelvic inflammatory disease are more common in HIV-infected women than in uninfected women. These manifestations also tend to be more severe when they occur in association with HIV infection. Therefore, HIV-infected women need frequent gynecologic care. Vaginal candidiasis may be treated with topical agents (see

Chapter 36: Mycotic Infections). However, HIV-infected women with recurrent or severe vaginal candidiasis may need systemic therapy.

The incidence of cervical dysplasia in HIV-infected women is 40%. Because of this finding, HIV-infected women should have Papanicolaou smears every 6 months (as opposed to the Agency for Healthcare Research and Quality [AHRQ] Guideline recommendation for every 12 months). Some clinicians recommend routine colposcopy or cervicography because cervical intraepithelial neoplasia has occurred in women with negative Papanicolaou smears. Cone biopsy is indicated in cases of serious cervical dysplasia. For 1 year following treatment of an abnormal Papanicolaou smear, women should have repeat smears every 3 to 4 months.

Cervical neoplasia appears to be more aggressive among HIV-infected women. Most HIV-infected women with cervical cancer die of that disease rather than of AIDS. Because of its frequency and severity, cervical neoplasia was added to the CDC definition of AIDS in 1993.

While pelvic inflammatory disease appears to be more common in HIV-infected women, the bacteriology of this condition appears to be the same as among HIV-uninfected women. At present, HIV-infected women with pelvic inflammatory disease should be treated with the same regimens as uninfected women (see Chapter 18:

Gynecologic Disorders). However, inpatient therapy is generally recommended.

Coronary artery disease

HIV-infected persons are at higher risk for coronary artery disease than age- and sex-matched controls. Part of this increase in coronary artery disease is due to changes in lipids caused by antiretroviral agents (see Treatment section on Antiretroviral Therapy below), especially stavudine and most of the protease inhibitors. However, some of the risk appears to be due to HIV infection, independent of its therapy. It is important that clinicians pay close attention to this issue because the first presentation of coronary artery disease in HIV-infected persons may be sudden death. HIV-infected patients with symptoms of coronary artery disease such as chest pain or dyspnea should be rapidly evaluated. Clinicians should aggressively treat conditions that result in increased risk of heart disease, especially smoking, hypertension, hyperlipidemia, obesity, diabetes mellitus, and sedentary lifestyle.

Inflammatory reactions (immune reconstitution syndromes)

With initiation of HAART, some patients experience inflammatory reactions that appear to be associated with immune reconstitution as indicated by a rapid increase in

CD4 count. These inflammatory reactions may present with generalized signs of fevers, sweats, and malaise with or without more localized manifestations that usually represent unusual presentations of opportunistic infections. For example, vitreitis has developed in patients with CMV retinitis after they have been treated with HAART. *M avium* can present as focal lymphadenitis or granulomatous masses in patients receiving HAART. Tuberculosis may paradoxically worsen with new or evolving pulmonary infiltrates and lymphadenopathy. PML and cryptococcal meningitis may also behave atypically. Clinicians should be alert to these syndromes, which are most often seen in patients who have initiated antiretroviral therapy in the setting of advanced disease and who show rapid increases in CD4 counts with treatment. The diagnosis of IRIS is one of exclusion and can be made only after recurrence or new opportunistic infection has been ruled out as the cause of the clinical deterioration. Management of IRIS is conservative and supportive with use of corticosteroids only for severe reactions. Most authorities recommend that antiretroviral therapy be continued unless the reaction is life-threatening.

Laboratory Findings

Specific tests for HIV include antibody and antigen detection (Table 31–2). Conventional HIV antibody testing is done by ELISA. Positive specimens are then confirmed by a different method (eg, Western blot). The sensitivity of screening serologic tests is greater than 99.5%. The specificity of positive results by two different techniques approaches 100% even in low-risk populations. False-positive screening tests may occur as normal biologic variants or in association with recent influenza vaccination or other disease states, such as connective tissue disease. These are usually detected by negative confirmatory tests. Molecular biology techniques (PCR) show a small incidence of individuals (< 1%) who are infected with HIV for up to 36 months without generating an antibody response. However, antibodies that are detectable by screening serologic tests will develop in 95% of persons within 6 weeks after infection.

Table 31–2. Laboratory findings with HIV infection.

Test	**Significance**
HIV enzyme-linked immunosorbent assay (ELISA)	Screening test for HIV infection. Of ELISA tests 50% are positive within 22 days after HIV transmission; 95% are positive within 6 weeks after transmission. Sensitivity > 99.9%; to avoid false-positive results, repeatedly reactive results must be confirmed with Western blot.

Western blot	Confirmatory test for HIV. Specificity when combined with ELISA > 99.99%. Indeterminate results with early HIV infection, HIV-2 infection, autoimmune disease, pregnancy, and recent tetanus toxoid administration.
HIV rapid antibody test	Screening test for HIV. Produces results in 10–20 minutes. Can be performed by personnel with limited training. Positive results must be confirmed with standard HIV test (ELISA and Western blot).
Complete blood count	Anemia, neutropenia, and thrombocytopenia common with advanced HIV infection.
Absolute CD4 lymphocyte count	Most widely used predictor of HIV progression. Risk of progression to an AIDS opportunistic infection or malignancy is high with CD4 < 200 cells/mcL in the absence of treatment.
CD4 lymphocyte percentage	Percentage may be more reliable than the CD4 count. Risk of progression to an AIDS opportunistic infection or malignancy is high with percentage

	< 14% in the absence of treatment.
HIV viral load tests	These tests measure the amount of actively replicating HIV virus. Correlate with disease progression and response to antiretroviral drugs. Best tests available for diagnosis of acute HIV infection (prior to seroconversion); however, caution is warranted when the test result shows low-level viremia (ie, <500 copies/mL) as this may represent a false-positive test.

Rapid HIV antibody tests are now available. They provide results within 10–20 minutes and can be performed in physician offices, including by personnel without laboratory training and without a Clinical Laboratory Improvement Amendment (CLIA) approved laboratory. Persons who test positive on a rapid test should be told that they may be HIV-infected or their test may be falsely reactive. Standard testing (ELISA with Western blot confirmation) should be performed to distinguish these two possibilities. Rapid testing is particularly helpful in settings where a result is needed immediately (eg, a woman in labor who has not recently been tested for HIV) or when the patient is unlikely to return for a result.

Nonspecific laboratory findings with HIV infection may include anemia, leukopenia (particularly lymphopenia), and thrombocytopenia in any combination, elevation of the erythrocyte sedimentation rate, polyclonal hypergammaglobulinemia, and hypocholesterolemia. Cutaneous anergy is common.

Several laboratory markers are available to provide prognostic information and guide therapy decisions (Table 31–2). The most widely used marker is the absolute CD4 lymphocyte count. As counts decrease, the risk of serious opportunistic infection over the subsequent 3–5 years increases (Figure 31–1: illustration).

There are many limitations to using the CD4 count, including diurnal variation, depression with intercurrent illness, and intralaboratory and interlaboratory variability. Therefore, the trend is more important than a single determination. The frequency of performance of counts depends on the patient's health status. Patients whose CD4 counts are substantially above the threshold for initiation of antiviral therapy (350 cells/mcL) should have counts performed every 6 months. Those who have counts near or below 350 cells/mcL should have counts performed every 3 months. This is necessary for evaluating the efficacy of antiviral therapy and for initiating *P jiroveci* prophylactic therapy when the CD4 count drops below 200 cells/mcL. Some studies suggest that the percentage of CD4 lymphocytes is a more reliable indicator of prognosis than the absolute counts because the percentage does not depend on calculating a manual differential. While the CD4 count measures immune dysfunction, it does not provide a measure of how actively HIV is replicating in the body. HIV viral load tests (discussed below) assess the level of viral replication and provide useful prognostic information that is independent of the information provided by CD4 counts.

Differential Diagnosis

HIV infection may mimic a variety of other medical illnesses. Specific differential diagnosis depends on the mode of presentation. In patients presenting with constitutional symptoms such as weight loss and fevers, differential considerations include cancer, chronic infections such as tuberculosis and endocarditis, and endocrinologic diseases such as hyperthyroidism. When pulmonary processes dominate the presentation, acute and chronic lung infections must be considered as well as other causes of diffuse interstitial pulmonary infiltrates. When neurologic disease is the mode of presentation, conditions that cause mental status changes or neuropathy—eg, alcoholism, liver disease, kidney dysfunction, thyroid disease, and vitamin deficiency—should be considered. If a patient presents with headache and a cerebrospinal fluid pleocytosis, other causes of chronic meningitis enter the differential. When diarrhea is a prominent complaint, infectious enterocolitis, antibiotic-associated colitis, inflammatory bowel disease, and malabsorptive symptoms must be considered.

Prevention

Primary Prevention

Until vaccination is a reality, prevention of HIV infection will depend on effective precautions regarding sexual practices and injection drug use, use of perinatal HIV prophylaxis, screening of blood products, and infection control practices in the health care setting. Primary care clinicians should routinely obtain a sexual history and provide risk factor assessment of their patients. Because approximately one-fourth of the HIV-infected persons in the United States do not know they are infected, the CDC recommends all adults be routinely tested for HIV. Prior to testing, clinicians should obtain informed consent and review the risk factors for HIV infection with the patient and discuss safer sex and safer needle use as well as the meaning of a positive test. For persons whose test results are positive, information on available medical and mental health services should be provided as well as guidance for contacting sexual or needle-sharing partners. Interventions focused on the importance of HIV-infected persons not putting others at risk have been successful. For patients whose test results are negative, clinicians should review safer sex and needle use practices, including counseling not to exchange bodily fluids unless they are in a long-term mutually monogamous relationship with someone who has tested HIV antibody-negative and has not engaged in unsafe sex, injection drug use, or other HIV risk behaviors for at least 6 months prior to or at any time since the negative test.

Only latex condoms should be used, along with a water-soluble lubricant. Although nonoxynol-9, a spermicide, kills HIV, it is contraindicated because in some patients it may cause genital ulcers that could facilitate HIV transmission. Patients should be counseled that condoms are not 100% effective. They should be made familiar with the use of condoms, including, specifically, the advice that condoms must be used every time, that space should be left at the tip of the condom as a receptacle for semen, that intercourse with a condom should not be attempted if the penis is only partially erect, that men should hold on to the base of the condom when withdrawing the penis to prevent slippage, and that condoms should not be reused. Although anal intercourse remains the sexual practice at highest risk for transmitting HIV, seroconversions have been documented with vaginal and oral intercourse as well. Therefore, condoms should be used when engaging in these activities. Women as well as men should understand how to use condoms so as to be sure that their partners are using them correctly. A randomized trial in Africa demonstrated that male circumcision significantly reduced HIV incidence in men, but there are a number of barriers to performing widespread circumcisions among men in Africa.

Persons using injection drugs should be cautioned never to exchange needles or other drug paraphernalia. When sterile needles are not available, bleach does appear to inactivate HIV and should be used to clean needles.

Current efforts to screen blood and blood products have lowered the risk of HIV transmission with transfusion of a unit of blood to 1:1,000,000.

In the hospital, concerns about nosocomial infection have led to the recommendation for universal body fluid precautions. This involves the rigorous use of gloves when handling any body fluid and the addition of gown, mask, and goggles for procedures that may result in splash or droplet spread as well as the use of specially designed needles with sheath devices to decrease the risk of needle sticks. Reports of transmission of drug-resistant tuberculosis in health care settings also have had infection control implications. All patients with cough in outpatient settings should be encouraged to wear masks. Hospitalized HIV-infected patients with cough should be placed in respiratory isolation until tuberculosis can be excluded by chest radiograph and sputum smear examination.

Primate model data have suggested that development of a protective vaccine may be possible, but clinical trials in humans using gp120 or its precursor gp160 have shown development of neutralizing antibodies to laboratory but not field isolates of HIV and may not be protective of infection. Many scientists have abandoned the quest for a fully protective HIV vaccine and are focusing on developing a vaccine that would reduce the chances of HIV transmission given a particular exposure.

Secondary Prevention

In the era prior to the development of highly effective antiretroviral treatment, cohort studies of individuals with documented dates of seroconversion demonstrate that AIDS develops within 10 years in approximately 50% of untreated seropositive persons. With currently available treatment, progression of disease has been markedly decreased. In addition to antiretroviral treatment, prophylactic regimens can prevent opportunistic infections and improve survival. Prophylaxis and early intervention prevent several infectious diseases, including tuberculosis and syphilis, which are transmissible to others. Recommendations for screening tests, vaccinations, and prophylaxis are listed in Table 31–3.

Table 31–3. Health care maintenance of HIV-infected individuals.
For all HIV-infected individuals:
CD4 counts every 3–6 months
Viral load tests every 3–6 months and 1 month following a change in therapy
PPD
INH for those with positive PPD and normal chest radiograph
RPR or VDRL
Toxoplasma IgG serology
Hepatitis serologies: hepatitis A antibody, hepatitis B

surface antigen, hepatitis B surface antibody, hepatitis B core antibody, hepatitis C antibody.
Pneumococcal vaccine
Inactivated influenza vaccine in season
Hepatitis A vaccine for those without immunity to hepatitis A.
Hepatitis B vaccine for those who are hepatitis B surface antigen and antibody negative. (Use 40 mcg formulation at 0, 1, and 6 months; repeat if no immunity 1 month after three-shot series.)
Tetanus/diphtheria vaccine
Human papillomavirus vaccine for HIV-infected women age 26 years or less.
Haemophilus influenzae type b vaccination
Papanicolaou smears every 6 months for women
Consider anal swabs for cytologic evaluation.
For HIV-infected individuals with CD4 < 200 cells/mcL:
Pneumocystis jiroveci prophylaxis (see Prophylaxis of Opportunistic Infections section under Treatment and Table 31–4)
For HIV-infected individuals with CD4 < 75 cells/mcL:
Mycobacterium avium complex prophylaxis (see Prophylaxis of Opportunistic Infections section under

Treatment)
For HIV-infected individuals with CD4 < 50 cells/mcL:
Consider CMV prophylaxis

PPD, purified protein derivative; INH, isoniazid; RPR, rapid plasma reagin; VDRL, Venereal Disease Research Laboratories; IgG, immunoglobulin G.

Because of the increased occurrence of tuberculosis among HIV-infected patients, all such individuals should undergo PPD testing. Although anergy is common among AIDS patients, the likelihood of a false-negative result is much lower when the test is done early in infection. Those with positive tests (defined for HIV-infected patients as > 5 mm of induration) need a chest radiograph. Patients with an infiltrate in any location, especially if accompanied by mediastinal adenopathy, should have sputum sent for acid-fast staining. Patients with a positive PPD but negative evaluations for active disease should receive isoniazid (300 mg daily) with pyridoxine (50 mg daily) for 9 months to a year. An alternative regimen of rifampin plus pyrazinamide for 2 months is no longer recommended because of the high associated incidence of hepatotoxicity. Recent analysis suggests also that HIV-infected individuals at high risk for tuberculosis should receive a course of isoniazid prophylaxis regardless of the

PPD status. This may include homeless individuals and injection drug users. Although not yet widely available, a blood test (QuantiFERON Gold test) can be used to assess prior tuberculosis exposure. Blood samples are mixed with synthetic antigens representing *M tuberculosis*. Patients infected with *M tuberculosis* produce interferon-gamma in response to contact with the antigens. Unlike the PPD, the patient does not have to return for a second visit. The test is less likely to result in false-positive results than a PPD. Unfortunately, HIV-infected persons may not produce sufficient interferon-gamma, in which case the test may be falsely negative.

Because of recent increases in the number of cases of syphilis among MSM, including those who are HIV infected, all such men should be screened for syphilis by rapid plasma reagin (RPR) or Venereal Disease Research Laboratories (VDRL) test every 6 months. Increases of syphilis cases among HIV-infected persons are of particular concern because these individuals are at increased risk for reactivation of syphilis and progression to tertiary syphilis despite standard treatment. Because the only widely available tests for syphilis are serologic and because HIV-infected individuals are known to have disordered antibody production, there is concern about the interpretation of these titers. This concern has been fueled by a report of an HIV-infected patient with secondary syphilis and negative syphilis serologic testing.

Furthermore, HIV-infected individuals may lose fluorescent treponemal antibody absorption (FTA-ABS) reactivity after treatment for syphilis, particularly if they have low CD4 counts. Thus, in this population, a nonreactive treponemal test does not rule out a past history of syphilis. In addition, persistence of treponemes in the spinal fluid after one dose of benzathine penicillin has been demonstrated in HIV-infected patients with primary and secondary syphilis. Therefore, the CDC has recommended an aggressive diagnostic approach to HIV-infected patients with reactive RPR or VDRL tests of greater than 1 year or unknown duration. All such patients should have a lumbar puncture with cerebrospinal fluid cell count and cerebrospinal fluid VDRL. Those with a normal cerebrospinal fluid evaluation are treated as having late latent syphilis (benzathine penicillin G, 2.4 million units intramuscularly weekly for 3 weeks) with follow-up titers. Those with a pleocytosis or a positive cerebrospinal fluid-VDRL test are treated as having neurosyphilis (aqueous penicillin G, 2–4 million units intravenously every 4 hours, or procaine penicillin G, 2.4 million units intramuscularly daily, with probenecid, 500 mg four times daily, for 10 days). Some clinicians take a less aggressive approach to patients who have low titers (less than 1:8), a history of having been treated for syphilis, and a normal neurologic examination. Close follow-up of titers is mandatory if such a course is taken. For a more detailed discussion of this topic, see Chapter

HIV-infected individuals should receive the pneumococcal vaccine and the inactivated influenza vaccine. Patients without immunity to hepatitis A should be vaccinated against it. Patients without evidence of hepatitis B surface antigen or surface antibody should receive hepatitis B vaccination, using the 40 mcg formulation; the higher dose is to increase the chance of developing protective immunity. If the patient does not have immunity 1 month after the three-shot series, then the series should be repeated. HIV-infected persons should also receive the standard inactivated vaccines such as tetanus and diphtheria boosters that would be given to uninfected persons. Live vaccines, such as yellow fever vaccine, should be avoided. Measles vaccination, while a live virus vaccine, appears relatively safe when administered to HIV-infected individuals and should be given if the patient has never had measles or been adequately vaccinated. Herpes zoster vaccine is contraindicated in HIV-infected persons with evidence of immune suppression.

A randomized study found that multivitamin supplementation decreased HIV disease progression and mortality in HIV-infected women in Africa. However, supplementation is unlikely to be as effective in well-nourished populations.

HIV-infected individuals should be counseled with regard to safe sex. Because of the risk of transmission, they should be warned to use condoms with sexual intercourse, including oral intercourse. Partners of HIV-infected women should use latex barriers such as dental dams (available at dental supply stores) to prevent direct oral contact with vaginal secretions. Substance abuse treatment should be recommended for persons who are using recreational drugs. They should be warned to avoid consuming raw meat or eggs to avoid infections with *Toxoplasma*, *Campylobacter*, and *Salmonella*. HIV-infected patients should wash their hands thoroughly after cleaning cat litter or should forgo this household chore to avoid possible exposure to toxoplasmosis. To reduce the likelihood of infection with *Bartonella* species, patients should avoid activities that might result in cat scratches or bites. Although the data are not conclusive, many clinicians recommend that HIV-infected persons—especially those with low CD4 counts—drink bottled water instead of tap water to prevent cryptosporidia infection.

Because of the emotional impact of HIV infection and subsequent illness, many patients will benefit from supportive counseling.

HIV Risk for Health Care Professionals

Epidemiologic studies show that needle sticks occur commonly among health care professionals, especially among surgeons performing invasive procedures, inexperienced hospital house staff, and medical students. Efforts to reduce needle sticks should focus on avoiding recapping needles and use of safety needles whenever doing invasive procedures under controlled circumstances. The risk of HIV transmission from a needle stick with blood from an HIV-infected patient is about 1:300. The risk is higher with deep punctures, large inocula, and source patients with high viral loads. The risk from mucous membrane contact is too low to quantitate.

Health care professionals who sustain needle sticks should be counseled and offered HIV testing as soon as possible. HIV testing is done to establish a negative baseline for worker's compensation claims in case there is a subsequent conversion. Follow-up testing is usually performed at 6 weeks, 3 months, and 6 months.

A case-control study by the CDC indicates that administration of zidovudine following a needle stick decreases the rate of HIV seroconversion by 79%. Therefore, providers should be offered therapy with Combivir (zidovudine 300 mg plus lamivudine 150 mg orally twice daily). Providers who have exposures to persons who are likely to have antiretroviral drug resistance (eg, persons receiving therapy who have detectable viral loads) should have their therapy individualized, using at least two drugs to which the source is unlikely to be resistant. Some clinicians recommend triple combination regimens, including a protease inhibitor for all occupational exposures, because of uncertainty about drug resistance. Others save these more aggressive regimens for the higher-risk exposures listed above. Because reports have noted hepatotoxicity due to nevirapine in this setting, this agent should be avoided. Therapy should be started as soon as possible after exposure and continued for 4 weeks. Unfortunately, there have been documented cases of seroconversion following potential parenteral exposure to HIV despite prompt use of zidovudine prophylaxis. Counseling of the provider should include "safer sex" guidelines.

Postexposure Prophylaxis for Sexual and Drug Use Exposures to HIV

Following publication of a case-control study indicating that antiretroviral therapy decreased the odds of seroconversion among health care workers who had occupational exposure, some experts have recommended offering antiretroviral therapy following potential exposure to HIV through sexual activity or drug use. Although there are no efficacy data to support this practice, there are similarities between the immune response following transcutaneous and transmucosal exposures. The goal of postexposure prophylaxis is to reduce or prevent local viral replication prior to dissemination such that the infection can be aborted.

The choice of antiretroviral agents and the duration of treatment are the same as those for exposures that occur through the occupational route (see above). In contrast to those with occupational exposures, some individuals may present very late after exposure. Because the likelihood of success declines with length of time from HIV exposure, it is not recommended that treatment be offered after 72 hours. In addition, because the psychosocial issues involved with postexposure prophylaxis for sexual and drug use exposures are complex, it should be offered only in the context of prevention counseling. Counseling should focus on how to prevent future exposures. Clinicians needing more information on postexposure prophylaxis for occupational or nonoccupational exposures should contact the National Clinician's Post-exposure Hotline (1-888-448-4911; http://www.ucsf.edu/hivcntr/PEPline/).

Preventing Perinatal Transmission of HIV

A multicenter trial showed that when zidovudine is administered to women during pregnancy, labor, and delivery and to their newborns, the rate of HIV transmission is decreased by two-thirds. An observational trial demonstrated that zidovudine treatment is almost as effective when begun during labor or when administered only to the infant, as long as treatment is begun within 48 hours after birth. Nonetheless, treatment begun by at least the second trimester is still recommended. Many women are currently being offered combination antiretroviral treatment to further lower the risk of transmission. The availability of treatment makes it essential that all women who are pregnant or considering pregnancy be offered HIV counseling and testing. Many obstetricians recommend combination antiretroviral treatment, especially if zidovudine resistance is suspected. HIV-infected women receiving antiretroviral therapy in whom pregnancy is recognized during the first trimester should be counseled about the benefits and potential risks to the fetus of treatment during the first trimester. Because healthy mothers make healthy babies, continuation of therapy should be strongly considered. Because about half of fetal infections in non–breast-feeding women occur shortly before or during the birth process, antiretroviral therapy should be administered whenever a woman initiates perinatal care even if she did not begin therapy in the second trimester. Breast-feeding is thought to increase the rate of transmission by 10–20% and should be avoided.

Treatment

Treatment for HIV infection can be broadly divided into the following categories: (1) prophylaxis for opportunistic infections, malignancies, and other complications of HIV infection; (2) treatment of opportunistic infections, malignancies, and other complications of HIV infection; and (3) treatment of the HIV infection itself with combination ART.

Treatment regimens for HIV infection are constantly changing. Clinicians may obtain up-to-date information on new and experimental treatments by calling the AIDS Clinical Trials Information Service (ACTIS), 800-TRIALS-A (English and Spanish), and the National AIDS Hot Line, 800-342-AIDS (English), 800-344-SIDA (Spanish), and 800-AIDS-TTY (hearing-impaired).

Prophylactic Treatment of Complications of HIV Infection

In general, decisions about prophylaxis of opportunistic infections are based on the CD4 count, other evidence of severe immunosuppression (eg, oral candidiasis), and a history of having had the infection in the past. In the era prior to HAART, patients who started taking prophylactic regimens were maintained on them indefinitely. However, studies have shown that in patients with robust improvements in immune function—as measured by increases in CD4 counts above the levels that are used to initiate treatment—prophylactic regimens can safely be discontinued.

Because individuals with advanced HIV infection are susceptible to a number of opportunistic pathogens, the use of agents with activity against more than one pathogen is preferable. It has been shown, for example, that trimethoprim-sulfamethoxazole confers some protection against toxoplasmosis in individuals receiving this drug for *Pneumocystis* prophylaxis.

Prophylaxis against *Pneumocystis* pneumonia

Patients with CD4 counts below 200 cells/mcL, a CD4 lymphocyte percentage below 14%, or weight loss or oral candidiasis should be offered primary prophylaxis for *Pneumocystis* pneumonia. Patients with a history of *Pneumocystis* pneumonia should receive secondary prophylaxis until they have had a durable virologic response to HAART for at least 3–6 months and maintain a CD4 count of > 250 cells/mcL. Regimens for *Pneumocystis* prophylaxis are given in Table 31–4.

Table 31–4. *Pneumocystis jiroveci* prophylaxis.

Drug	**Dose**	**Side Effects**	**Limitations**
Trimethoprim-sulfamethoxazole	One double-strength	Rash, neutropenia, hepatitis, Stevens-Johnson syndrome	Hypersensitivity reaction is common but, if mild, it may be possible to

	tablet three times a week to one tablet daily		treat through.
Dapsone	50–100 mg daily or 100 mg two or three times per week	Anemia, nausea, methemoglobinemia, hemolytic anemia	Less effective than above. Glucose-6-phosphate dehydrogenase (G6PD) level should be checked prior to therapy. Check methemoglobin level at 1 month.
Atovaquone	1500 mg daily with a meal	Rash, diarrhea, nausea	Less effective than suspension trimethoprim-sulfamethoxazole; equal efficacy to

			dapsone, but more expensive.
Aerosolized pentamidine	300 mg monthly	Bronchospasm (pretreat with bronchodilators); rare reports of pancreatitis	Apical *Pneumocystis jiroveci* pneumonia, extrapulmonary *P jiroveci* infections, pneumothorax.

Prophylaxis against *M avium* complex infection

Patients whose CD4 counts fall to below 75–100 cells/mcL should be given prophylaxis against *M avium* complex infection. Clarithromycin (500 mg orally twice daily) and azithromycin (1200 mg orally weekly) have both been shown to decrease the incidence of disseminated *M avium* complex infection by approximately 75%, with a low rate of breakthrough of resistant disease. The azithromycin regimen is generally preferred based on high compliance and low cost. Adding rifabutin increases the toxicity of the regimen but does not significantly increase its efficacy and is therefore not recommended. Prophylaxis against *M avium* complex infection may be discontinued in patients whose CD4 counts rise above 100 cells/mcL in response to HAART and whose plasma viral load has been optimally suppressed to < 50–75 copies/mL.

Prophylaxis against *M tuberculosis* infection

Isoniazid, 300 mg daily, plus pyridoxine, 50 mg orally daily, for 9-12 months should be given to all HIV-infected patients with positive PPD reactions (defined as > 5 mm of induration for HIV-infected patients).

Prophylaxis against toxoplasmosis

Toxoplasmosis prophylaxis is desirable in patients with a positive IgG toxoplasma serology and CD4 counts below 100 cells/mcL. Trimethoprim-sulfamethoxazole (one double-strength tablet daily) offers good protection against toxoplasmosis, as does a combination of pyrimethamine, 25 mg orally once a week, plus dapsone, 50 mg orally daily, plus leucovorin, 25 mg orally once a week. A glucose-6-phosphate dehydrogenase (G6PD) level should be checked prior to dapsone therapy, and a methemoglobin level should be checked at 1 month.

Prophylaxis against CMV infection

Oral ganciclovir (1000 mg orally three times daily with food) is approved for CMV prophylaxis among HIV-infected persons with advanced disease (eg, CD4 counts below 50 cells/mcL). However, because the drug causes neutropenia, it is not widely used. Clinicians should consider performing serum CMV IgG antibody testing prior to starting ganciclovir. Persons who are CMV IgG-negative are not at risk for development of CMV disease, although it is important that such patients receive only CMV-negative blood if they require transfusion. Because over 99% of MSM are positive for CMV IgG, it is appropriate to reserve such testing for heterosexuals with HIV.

Prophylaxis against cryptococcosis, candidiasis, and endemic fungal diseases

One trial showed a decreased incidence of cryptococcal disease with prophylaxis using fluconazole, 200 mg orally daily, but the treated group had no benefit in terms of mortality. Fluconazole (200 mg orally once a week) was found to prevent oral and vaginal candidiasis in women with CD4 counts below 300 cells/mcL. In areas of the world where histoplasmosis and coccidioidomycosis are endemic and are frequent complications of HIV infection, prophylactic use of fluconazole or itraconazole may prove to be useful strategies. However, the problem of identifying individuals at highest risk makes appropriate targeting of prophylaxis difficult.

Treatment of Complications of HIV Infection

Treatment of common AIDS-related complications is detailed in Table 31–5. In the era prior to the use of HAART, patients required lifelong treatment for many infections, including CMV retinitis, toxoplasmosis, and cryptococcal meningitis. However, among patients who have a good response to HAART, maintenance therapy for some opportunistic infections can be terminated. For example, in consultation with an ophthalmologist, maintenance treatment for CMV infection can be discontinued when persons receiving HAART have durable suppression of viral load (ie, < 50 copies/mL) and a CD4 count > 100–150 cells/mcL. Similar results have been observed in patients with *M avium* complex bacteremia. Prophylaxis for *Pneumocystis* pneumonia is also commonly discontinued in patients who have achieved and maintained a CD4 > 200 cells/mcL with good virologic control.

Table 31–5. Treatment of AIDS-related opportunistic infections and malignancies.[1]

Infection or Malignancy	**Treatment**	**Complications**
Pneumocystis jiroveci infection[1]	Trimethoprim-sulfamethoxazole, 15 mg/kg/d (based on trimethoprim	Nausea, neutropenia, anemia, hepatitis, drug rash, Stevens-Johnson syndrome.

	component) orally or intravenously for 14–21 days.	
	Pentamidine, 3–4 mg/kg/d intravenously for 14–21 days.	Hypotension, hypoglycemia, anemia, neutropenia, pancreatitis, hepatitis.
	Trimethoprim, 15 mg/kg/d orally, with dapsone, 100 mg/d orally, for 14–21 days.[2]	Nausea, rash, hemolytic anemia in G6PD[2]-deficient patients. Methemoglobinemia (weekly levels should be < 10% of total hemoglobin).
	Primaquine, 15–30 mg/d orally, and clindamycin, 600 mg every 8 hours orally, for 14–21 days.	Hemolytic anemia in G6PD-deficient patients. Methemoglobinemia, neutropenia, colitis.
	Atovaquone, 750 mg orally three times daily for	Rash, elevated aminotransferases, anemia, neutropenia.

	14–21 days.	
	Trimetrexate, 45 mg/m^2 intravenously for 21 days (given with leucovorin calcium) if intolerant of all other regimens.	Leukopenia, rash, mucositis.
Mycobacterium avium complex infection	Clarithromycin, 500 mg orally twice daily with ethambutol, 15 mg/kg/d orally (maximum, 1 g). May also add:	Clarithromycin: hepatitis, nausea, diarrhea; ethambutol: hepatitis, optic neuritis.
	Rifabutin, 300 mg orally daily.	Rash, hepatitis, uveitis.
Toxoplasmosis	Pyrimethamine, 100–200 mg orally as loading dose, followed by 50–75 mg/d, combined with sulfadiazine, 4–6 g orally daily in	Leukopenia, rash.

	four divided doses, and folinic acid, 10 mg daily for 4–8 weeks; then pyrimethamine, 25–50 mg/d, with clindamycin, 2–2.7 g/d in three or four divided doses, and folinic acid, 5 mg/d, until clinical and radiographic resolution is achieved.	
Lymphoma	Combination chemotherapy (eg, modified CHOP, M-BACOD, with or without G-CSF or GM-CSF). Central nervous system disease: radiation treatment with	Nausea, vomiting, anemia, leukopenia, cardiac toxicity (with doxorubicin).

	dexamethasone for edema.	
Cryptococcal meningitis	Amphotericin B, 0.6 mg/kg/d intravenously, with or without flucytosine, 100 mg/kg/d orally in four divided doses for 2 weeks, followed by:	Fever, anemia, hypokalemia, azotemia.
	Fluconazole, 400 mg orally daily for 6 weeks, then 200 mg orally daily.	Hepatitis.
Cytomegalovirus infection	Valganciclovir, 900 mg orally twice a day for 21 days with food (induction), followed by 900 mg daily with food (maintenance).	Neutropenia, anemia, thrombocytopenia.
	Ganciclovir, 10	Neutropenia

	mg/kg/d intravenously in two divided doses for 10 days, followed by 6 mg/kg 5 days a week indefinitely. (Decrease dose for kidney disease.) May use ganciclovir as maintenance therapy (1 g orally with fatty foods three times a day).	(especially when used concurrently with zidovudine), anemia, thrombocytopenia.
	Foscarnet, 60 mg/kg intravenously every 8 hours for 10–14 days (induction), followed by 90 mg/kg once daily. (Adjust for changes in kidney function.)	Nausea, hypokalemia, hypocalcemia, hyperphosphatemia, azotemia.

Esophageal candidiasis or recurrent vaginal candidiasis	Fluconazole, 100–200 mg orally daily for 10–14 days.	Hepatitis, development of imidazole resistance.
Herpes simplex infection	Acyclovir, 400 mg orally three times daily until healed; or acyclovir, 5 mg/kg intravenously every 8 hours for severe cases.	Resistant herpes simplex with chronic therapy.
	Famciclovir, 500 mg orally twice daily until healed.	Nausea.
	Valacyclovir, 500 mg orally twice daily until healed.	Nausea.
	Foscarnet, 40 mg/kg intravenously every 8 hours, for acyclovir-resistant cases. (Adjust for changes in kidney	See above.

	function.)	
Herpes zoster	Acyclovir, 800 mg orally four or five times daily for 7 days. Intravenous therapy at 10 mg/kg every 8 hours for ocular involvement, disseminated disease.	See above.
	Famciclovir, 500 mg orally three times daily for 7 days.	Nausea.
	Valacyclovir, 500 mg orally three times daily for 7 days.	Nausea.
	Foscarnet, 40 mg/kg intravenously every 8 hours for acyclovir-resistant cases. (Adjust for	See above.

	changes in kidney function.)	
Kaposi sarcoma		
Limited cutaneous disease	Observation, intralesional vinblastine.	Inflammation, pain at site of injection.
Extensive or aggressive cutaneous disease	Systemic chemotherapy (eg, liposomal doxorubicin). Interferon- (for patients with CD4 > 200 cells/mcL and no constitutional symptoms). Radiation (amelioration of edema).	Bone marrow suppression, peripheral neuritis, flu-like syndrome.
Visceral disease (eg, pulmonary)	Combination chemotherapy (eg, daunorubicin, bleomycin, vinblastine).	Bone marrow suppression, cardiac toxicity, fever.

[1] For moderate to severe *P jiroveci* infection (oxygen saturation < 90%), corticosteroids should be given with specific treatment. The dose of prednisone is 40 mg orally twice daily for 5 days, then 40 mg daily for 5 days, and then 20 mg daily until therapy is complete.

[2] When considering use of dapsone, check glucose-6-phosphate dehydrogenase (G6PD) level in black patients and those of Mediterranean origin.

CHOP, cyclophosphamide, doxorubicin (hydroxydaunomycin), vincristine (Oncovin), and prednisone; G-CSF, granulocyte-colony stimulating factor (filgrastim); GM-CSF, granulocyte-macrophage colony-stimulating factor (sargramostim); modified M-BACOD, methotrexate, bleomycin, doxorubicin (Adriamycin), cyclophosphamide, vincristine (Oncovin), and dexamethasone.

Treating patients with repeated episodes of the same opportunistic infection can pose difficult therapeutic challenges. For example, patients with second or third episodes of *Pneumocystis* pneumonia may have developed allergic reactions to standard treatments with a prior episode. Fortunately, there are several alternatives available for the treatment of *Pneumocystis* infection. Trimethoprim with dapsone and primaquine with clindamycin are two combinations that often are tolerated in patients with a prior allergic reaction to trimethoprim-sulfamethoxazole and intravenous pentamidine. On the positive side, patients in whom second episodes of *Pneumocystis* pneumonia develop while taking prophylaxis tend to have milder courses.

Well-established alternative regimens now also exist for most AIDS-related opportunistic infections: amphotericin B or fluconazole for cryptococcal meningitis; ganciclovir, cidofovir, or foscarnet for CMV infection; and sulfadiazine or clindamycin with pyrimethamine for toxoplasmosis.

Adjunctive Treatments

Although conceptually it would seem that **corticosteroids** should be avoided in HIV-infected patients, corticosteroid therapy has been shown to improve the course of patients with moderate to severe *Pneumocystis jiroveci* pneumonia (oxygen saturation < 90%, Po_2 < 65 mm Hg) when administered within 72 hours after diagnosis. The mechanism of action is presumed to be a decrease in alveolar inflammation.

Corticosteroids have also been used to treat immune reconstitution and inflammatory syndromes (IRIS) that can sometimes complicate the early treatment course when ART is initiated in patients with advanced AIDS (see section Inflammatory reactions [immune reconstitution syndromes]).

Epoetin alfa (erythropoietin) is approved for use in HIV-infected patients with anemia, including those with anemia secondary to zidovudine use. It has been shown to decrease the need for blood transfusions. The drug is expensive, and therefore an erythropoietin level < 500 mU/mL should be demonstrated before starting therapy. The starting dose of epoetin alfa is 8000 units subcutaneously three times a week. The target hematocrit is 35–40%. The dose may be increased by 12,000 units every 4–6 weeks as needed to a maximum dose of 48,000 units per week. Hypertension is the most common side effect.

Human G-CSF (filgrastim) and **granulocyte-macrophage colony-stimulating factor (GM-CSF [sargramostim])** have been shown to increase the neutrophil counts of HIV-infected patients. Because of the high cost of this therapy, the dosage should be closely monitored and minimized, aiming for a neutrophil count of 1000/mcL. When the drug is used for indications other than cytotoxic chemotherapy, one or two doses at 5 mcg/kg per week are usually sufficient.

Antiretroviral Therapy

The availability of agents that in combination suppress HIV replication (Table 31–6) has had a profound impact on the natural history of HIV infection. Patients who achieve excellent suppression of HIV generally have stabilization or improvement of their clinical course that results from immunologic reconstitution and a subsequent decrease in AIDS-related complications. The greater potency and the improved side effect profile have led to recommendations to start treatment earlier in the course of HIV disease. Treatment should be initiated for all symptomatic patients, and for asymptomatic persons who (1) have CD4 cell counts below 350 cells/mcL; (2) have rapidly dropping CD4 counts or very high viral loads (> 100,000/mcL); (3) have dual infection with hepatitis B or C (rapid HIV replication is thought to hasten progression of hepatitis B and C); (4) have risk factors for cardiac disease (rapid HIV replication may increase the risk of cardiac disease); or (5) have risk factors for non–AIDS-related cancers (rapid HIV replication may increase such cancers). However, for patients who might have difficulty adhering to such therapy, deferring ART for some time may be a better strategy. In addition, because 5–20% of patients in developed countries who are treatment-naïve have a virus that is resistant to some drugs, resistance testing is recommended for all patients prior to initiating ART.

Table 31–6. Antiretroviral therapy.

Drug	**Dose**	**Common Side Effects**	**Special Monitoring**[1]	**Cost**[2]	**Cost/Month**
Nucleoside reverse transcriptase inhibitors					
Zidovudine (AZT) (Retrovir)	600 mg orally daily in two divided doses	Anemia, neutropenia, nausea, malaise, headache, insomnia, myopathy	No special monitoring	$6.08/300 mg	$365.09
Didanosine (ddI) (Videx)	400 mg orally daily (enteric-coated capsule) for person	Peripheral neuropathy, pancreatitis, dry mouth, hepatitis	Bimonthly neurologic questionnaire for neuropathy, K^+,	$10.70/400 mg	$321.00

	s 60 kg		amylase, bilirubin, triglycerides		
Zalcitabine (ddC) (Hivid)	0.375–0.75 mg orally three times daily	Peripheral neuropathy, aphthous ulcers, hepatitis	Monthly neurologic questionnaire for neuropathy	$3.03/0.75 mg	$272.70
Stavudine (d4T) (Zerit)	40 mg orally twice daily for persons 60 kg	Peripheral neuropathy, hepatitis, pancreatitis	Monthly neurologic questionnaire for neuropathy, amylase	$7.31/40 mg	$438.61

Lamivudine (3TC) (Epivir)	150 mg orally twice daily	Rash, peripheral neuropathy	No special monitoring	$6.80/150 mg	$408.00
Emtricitabine (Emtriva)	200 mg orally once daily	Skin discoloration palms/soles (mild)	No special monitoring	$13.15/200 mg	$394.38
Abacavir (Ziagen)	300 mg orally twice daily	Rash, fever—if occur, rechallenge may be fatal	No special monitoring	$9.14/300 mg	$548.21
Nucleotide reverse transcriptase inhibitors					
Tenofovir (Viread)	300 mg orally once daily	Gastrointestinal distress	Kidney function	$22.09/300 mg	$662.70
Protease inhibitors (PIs)					
Indinavir (Crixivan)	800 mg orally	Renal calculi	Cholesterol, triglyc	$3.05/400 mg	$548.12

	three times daily		erides, bilirubin level		
Saquinavir hard gel (Invirase)	1000 mg orally twice daily with 100 mg ritonavir orally twice daily	Gastrointestinal distress	Cholesterol, triglycerides	$6.91/500 mg	$829.18 (plus cost of ritonavir)
Ritonavir (Norvir)	600 mg orally twice daily or in lower doses (eg,	Gastrointestinal distress, peripheral paresthesias	Cholesterol, triglycerides	$10.29/100 mg	$3703.20($617.20 in lower doses)

	100 mg orally once or twice daily) for boosting other PIs				
Nelfinavir (Viracept)	750 mg orally three times daily or 1250 mg twice daily	Diarrhea	Cholesterol, triglycerides	$2.52/250 mg $6.30/625 mg	$680.99 $726.40
Fosamprenavir (Lexiva)	For PI-experienced patients: 700 mg	Gastrointestinal rash	Cholesterol, triglycerides	$12.91/700 mg	$774.52 – $1549.04 (plus cost of ritonavir

	orally twice daily and 100 mg of ritonavir 100 orally twice daily. For PI-naïve patients: above or 1400 mg orally twice daily or 1400 mg orally once				for lower dose)

	daily and 200 mg of ritonavir orally once daily				
Lopinavir/ritonavir (Kaletra)	400 mg/100 mg orally twice daily	Diarrhea	Cholesterol, triglycerides	$7.02/200 mg (lopinavir)	$841.90
Atazanavir (Reyataz)	400 mg orally once daily	Hyperbilirubinemia	Bilirubin level; when used with ritonavir: cholesterol and triglyc	$17.12/200 mg	$1026.90

			erides		
Tipranavir/ritonavir (Aptivus/Norvir)	500 mg of tipranavir and 200 mg of ritonavir orally twice daily	Gastrointestinal, rash	Cholesterol, triglycerides	$8.94/250 mg (tipranavir)$10.29/100 mg (ritonavir)	$2307.20 (for combination)
Darunavir/ritonavir (Prezista/Norvir)	600 mg of darunavir and 100 mg of ritonavir orally twice daily	Rash	Cholesterol, triglycerides	$7.80/300 mg (darunavir)$10.29/100 mg (ritonavir)	$1553.40 (for combination)
Nonnucleoside reverse transcriptase inhibitors (NNRTIs)					
Nevirapine	200 mg	Rash	No specia	$8.56/200 mg	$513.80

(Viramune)	orally daily for 2 weeks, then 200 mg orally twice daily		l monitoring		
Delavirdine (Rescriptor)	400 mg orally three times daily	Rash	No special monitoring	$1.69/200 mg	$303.70
Efavirenz (Sustiva)	600 mg orally daily	Neurologic disturbances	No special monitoring	$20.07/600 mg	$602.00
Etravirine (Intelence)	200 mg orally daily	Rash, nausea	No special monitoring		
Entry inhibitors					

Enfuvirtide (Fuzeon)	90 mg subcutaneously twice daily	Injection site pain and allergic reaction	No special monitoring	$42.89/90 mg	$2573.16
Maraviroc (Selzentry)	150–300 mg orally daily	Cough, fever, rash	No special monitoring	$17.40/150 mg or 300 mg	$1044.00
Integrase inhibitor					
Raltegravir(Isentress)	400 mg orally twice daily	Diarrhea, nausea, headache	No special monitoring	$16.20/400 mg	$972.00

[1] Standard monitoring is complete blood count (CBC) and differential, and serum aminotransferases.

[2] Average wholesale price (AWP, for AB-rated generic when available) for quantity listed. Source: *Red Book Update*, Vol. 28, No. 3, March 2009. AWP may not accurately represent the actual pharmacy cost because wide contractual variations exist among institutions.

Once a decision to initiate therapy has been made, several important principles should guide therapy. First, because drug resistance to antiretroviral agents develops in HIV-infected patients, a primary goal of therapy should be complete suppression of viral replication as measured by the serum viral load. Therapy that achieves a plasma viral load of < 40 or < 50 copies/mL (depending on the test used) has been shown to provide a durable response to the therapy. To achieve this and maintain virologic control over time, combination therapy with at least 3 drugs from at least two different classes is necessary, and partially suppressive combinations such as dual nucleoside therapy should be avoided. Similarly, if toxicity develops, it is preferable to either interrupt the entire regimen or change the offending drug rather than reduce individual doses.

A recent randomized trial compared early initiation of ART (within 2 weeks of starting treatment for an opportunistic infection) with ART that was deferred until after treatment of the opportunistic infection was completed (6 weeks after its start); results demonstrated that early initiation reduced death or AIDS progression by 50%. The reduced progression rates were related to more rapid improvements in CD4 counts in patients with advanced immunodeficiency. Furthermore, IRIS and other adverse events were no more frequent in the early ART arm. Based on these results, most treatment guidelines recommend that ART be initiated as early as is clinically feasible for patients with an acute AIDS-related opportunistic infection. For hospitalized patients, this recommendation requires close coordination between inpatient and outpatient physicians to ensure that treatment is continued once patients are discharged.

The current standard is to use at least three agents simultaneously usually from at least two different classes. Because the number of drugs and potential combinations is finite and the development of drug resistance may severely compromise the efficacy of treatment, patients must be able to adhere to these regimens. Adherence can be promoted through the use of medication boxes with compartments (eg, Medisets), supportive counseling, or daily supervision of therapy. Therefore, decisions to withhold treatment should not be based on a patient's circumstances (eg, active drug use or housing status) alone. Often, a trial intervention such as offering *Pneumocystis* pneumonia prophylaxis may be helpful in determining the likelihood of adherence to a more complex antiretroviral regimen.

Monitoring of ART has two goals. Laboratory evaluation for toxicity depends on the specific drugs in the combination but generally should be done approximately every 3 months once a patient is on a stable regimen. Patients who are intolerant of their initial regimen (eg, patients who cannot tolerate the neurologic side effects of efavirenz) should be changed to an alternative drug or regimen. The second aspect of monitoring is to regularly measure objective markers of efficacy. The CD4 cell count and HIV viral load should be repeated 1–2 months after the initiation or change of antiretroviral regimen and every 3–4 months thereafter in clinically stable patients. In a patient who is adherent to an effective regimen, viral loads should be undetectable within 12–24 weeks. For patients in whom viral loads are not suppressed or who have viral rebound after suppression, the major question facing the clinician is whether the patient is nonadherent or has resistance to the regimen, or both. The issue is complicated because many patients report being more compliant than they really are, not because they wish to be untruthful but because they wish to tell the clinician what he or she wants to hear. Patients who are having trouble adhering to their treatment should receive counseling on how to better comply to their treatment. In patients who are adherent or who have missed enough doses to make resistance possible, resistance testing must be performed. Based on the results of resistance testing, and assessment of the patient's capability to comply with complicated regimens or to tolerate predictable side effects, the clinician should prescribe a combination of three medications to which there is no or only minimal resistance. Some patients whose counts rise dramatically on ART and who are fully suppressed (ie, plasma viral load < 50 copies/mL) may be successfully transitioned from a high potency regimen to a lower potency regimen with fewer side effects; however, this "induction-maintenance" strategy is still being evaluated in clinical trials. Stopping therapy in patients with high CD4 counts will generally result in patients reverting to their pretreatment nadir CD4 count in a matter of months and is therefore not recommended.

Although the ideal combination of drugs has not yet been defined for all possible clinical situations, possible choices can be better understood after a review of the available agents. These drugs can be grouped into five major categories: nucleoside and nucleotide reverse transcriptase inhibitors (NRTI), protease inhibitors (PI), nonnucleoside reverse transcriptase inhibitors (NNRTI), entry inhibitors (including fusion inhibitors and CCR5 antagonists), and integrase inhibitors. Once ART has been initiated in a patient, it is not advisable to stop the therapy unless there is a compelling reason (eg, toxicity, poor adherence, etc). So-called "drug holidays" or "structured treatment interruptions" have been shown to increase risk of AIDS-related complications, increase CD4 declines, and increase morbidity from non–AIDS-related complications (eg, myocardial infarctions and liver failure) and are not recommended.

Nucleoside and Nucleotide Reverse Transcriptase

Inhibitors

There are currently seven nucleoside or nucleotide agents approved for use. The choice of which agent to use depends primarily on the patient's prior treatment experience, results of resistance testing, drug side effects, other underlying conditions, and convenience of formulation. However, most clinicians use fixed-dose combinations of either tenofovir/emtricitabine (TDF/FTC) or abacavir/lamivudine (ABC/3TC), both of which can be given once a day. Zidovudine/lamivudine (AZT/3TC) is usually reserved for second- or third-line regimens because of toxicity and dosing schedule. Recent studies have raised some concerns about the efficacy of ABC/3TC in patients with high viral loads (eg, > 100,000 copies/mL) as well as concerns about increase risks of myocardial infarction with abacavir. Therefore, TDF/FTC is the preferred fixed-dose combination as part of initial treatment regimens.

Of the available agents, zidovudine is the most likely to cause anemia. Zidovudine and didanosine are the most likely to cause neutropenia. Stavudine is the most likely to cause lipoatrophy (loss of fat in the face, extremities, and buttocks) followed by zidovudine. Zalcitabine and didanosine are the most likely to cause peripheral neuropathy. Lamivudine, emtricitabine, and tenofovir have activity against hepatitis B. Didanosine, lamivudine, emtricitabine, and tenofovir can be administered daily. Generally, didanosine and tenofovir should not be given together due to toxicity of the combination that can result in decreasing CD4 counts. Information specific to each drug is given below, and recommendations on how to combine them appear in the Constructing Regimens section below.

Zidovudine

Zidovudine was the first approved antiviral drug for HIV infection and remains an important agent. It is administered at a dose of 300 mg orally twice daily. A combination of zidovudine 300 mg and lamivudine 150 mg (Combivir) allows more convenient dosing of medication for individuals taking both of these agents. Side effects seen with zidovudine are listed in Table 31–6. Approximately 40% of patients experience subjective side effects that usually remit within 6 weeks. The common dose-limiting side effects are anemia and neutropenia, which require ongoing laboratory monitoring. Long-term use has been associated with lipoatrophy.

Didanosine

The most convenient formulation of didanosine (ddI) is the enteric-coated capsule. For adults weighing at least 60 kg, the dose is one 400-mg enteric-coated capsule orally daily; for those 30–59 kg, the dose is one 250-mg enteric-coated capsule orally daily. Didanosine should be taken on an empty stomach.

Didanosine does not cause anemia but may cause neutropenia. It has also been associated with pancreatitis. The incidence of pancreatitis with didanosine is 5–10%—of fatal pancreatitis, less than 0.4%. Patients with a history of pancreatitis, as well as those taking other medications associated with pancreatitis (including trimethoprim-sulfamethoxazole and intravenous pentamidine) are at higher risk for this complication. Patients should be warned to use alcohol judiciously while taking didanosine. Other common side effects with didanosine include a dose-related, reversible, painful peripheral neuropathy, which occurs in about 15% of patients, and dry mouth. Fulminant hepatic failure and electrolyte abnormalities, including hypokalemia, hypocalcemia, and hypomagnesemia, have been reported in patients taking didanosine.

Stavudine

Stavudine (d4T) has shown good activity as an antiretroviral drug. The dose is 40 mg orally twice daily for individuals weighing 60 kg or more. However, because of its side effects including lipoatrophy, lipodystrophy (see below), peripheral neuropathy and, rarely, lactic acidosis and hepatitis, this drug should no longer be used except when there is no alternative.

Patients taking stavudine should be routinely changed to abacavir or tenofovir, both of which are less likely to cause lipoatrophy.

Lamivudine

Lamivudine (3TC) is a safe and well-tolerated agent. The dosage is 150 mg orally twice daily or 300 mg orally once a day. The dose should be reduced with chronic kidney disease. There are no significant side effects with lamivudine, and it has activity also against hepatitis B.

Emtricitabine

Emtricitabine is a nucleoside analog that is dosed at 200 mg orally. It was developed primarily as a once a day alternative to lamivudine. However, lamivudine can be dosed daily, eliminating the special indication for emtricitabine. As is true of lamivudine, emtricitabine has activity against hepatitis B and its dosage should be reduced in patients with chronic kidney disease.

Abacavir

A daily dose of 300 mg orally twice daily results in potent antiretroviral activity. Prior to initiation of abacavir, patients should undergo testing for HLA typing. Those with the B*5701 allele should not be treated with abacavir because the likelihood of a hypersensitivity reaction developing is high; the reaction is characterized by a flu-like syndrome with rash and fever that worsens with successive doses. Unfortunately, the absence of this allele does not guarantee that the patient will avoid the hypersensitivity reaction. Individuals in whom the hypersensitivity reaction develops *should not* be rechallenged with this agent because subsequent hypersensitivity reactions can be fatal. Two studies have reported an apparent increased risk of myocardial infarctions with abacavir use in patients who have underlying risks of cardiovascular disease. Consequently, abacavir should be avoided in such patients if effective alternative nucleoside or nucleotide analog agents exist.

Abacavir is formulated with zidovudine and lamivudine in a single pill (Trizivir, one tablet orally twice daily). Trizivir is not recommended as solo treatment for HIV because it is not as efficacious as combining two nucleoside/nucleotide analogs with a PI/ritonavir or an NNRTI; its use as a sole regimen should be reserved only for exceptional cases. Abacavir is also available as a fixed dose combination pill with lamivudine for use as a once daily pill (Epzicom).

Zalcitabine

Zalcitabine (ddC) is thought to be one of the least effective antiretroviral agents and is therefore not commonly used. Zalcitabine, like didanosine, may cause peripheral neuropathy. It is also associated with aphthous ulcers, rash, and rare cases of pancreatitis.

Tenofovir

Tenofovir is the only licensed nucleotide analog. It is given as a single daily oral dose of 300 mg and is generally well tolerated. Tenofovir is available in a fixed dose combination pill with emtricitabine (Truvada) for daily dosing and is the only recommended fixed-dose combination for initial regimens. A once-a-day single fixed-dose combination pill that contains tenofovir, emtricitabine, and efavirenz (Atripla) is also available. Tenofovir is active against hepatitis B, including isolates that have resistance to lamivudine.

Protease inhibitors

Ten PIs—indinavir, nelfinavir, ritonavir, saquinavir, amprenavir, fosamprenavir, lopinavir (in combination with ritonavir), atazanavir, darunavir, and tipranavir are available. PIs have been shown to potently suppress HIV replication and are administered as part of a combination regimen.

All the PIs—to differing degrees—are metabolized by the cytochrome P450 system, and each can inhibit and induce various P450 isoenzymes. Therefore, drug interactions are common and difficult to predict. Clinicians should consult the product inserts before prescribing PIs with other medications. Drugs such as rifampin that are known to induce the P450 system should be avoided.

The fact that the PIs are dependent on metabolism through the cytochrome P450 system has led to the use of ritonavir to boost the drug levels of saquinavir, lopinavir, indinavir, atazanavir, tipranavir, darunavir and amprenavir, allowing use of lower doses and simpler dosing schedules of these PIs. In fact, current guidelines recommend that all PI-containing regimens use ritonavir boosting if possible. The only PIs that can be safely used without ritonavir boosting are nelfinavir and atazanavir.

When choosing which PI to use, prior patient experience, resistance patterns, side effects, and ease of administration are the major considerations. The first three PIs to be developed—indinavir, saquinavir, and ritonavir (as single agents)—are now rarely used because of the superiority of the second generation of PIs. Amprenavir has been almost entirely replaced by its prodrug, fosamprenavir. Unfortunately, all PIs, with the exception of unboosted atazanavir have been linked to a constellation of metabolic abnormalities, including elevated cholesterol levels, elevated triglyceride levels, insulin resistance, diabetes mellitus, and changes in body fat composition (eg, buffalo hump, abdominal obesity). The lipid abnormalities and body habitus changes are referred to as lipodystrophy. Although lipodystrophy is commonly associated with PIs, it has been seen also in

HIV-infected persons who have never been treated with these agents. In particular, the lipoatrophy effects seen in patients receiving ART appears to be more related to the nucleoside toxicity and in particular to the thymidine analogs (stavudine and zidovudine).

Of the different manifestations of lipodystrophy, the dyslipidemias that occur are of particular concern because of the likelihood that increased levels of cholesterol and triglycerides will result in increased prevalence of heart disease. All patients taking PIs or NRTIs should have fasting serum cholesterol, low-density lipoprotein (LDL) cholesterol, and triglyceride levels performed every 3–6 months. Clinicians should calculate the Framingham 10-year coronary heart disease risk (see Chapter 28: Lipid Disorders) and consider initiating dietary or drug therapy (or both) to achieve target LDL levels depending on the individual's risk factors. Patients who are unable to meet their LDL goal based solely on dietary interventions should be given pravastatin (20 mg daily orally) or atorvastatin (10 mg daily orally). Lovastatin and simvastatin should be avoided because of their interactions with PIs. Fish oil (3000 mg daily) combined with exercise and dietary counseling has been found to decrease triglycerides levels by 25%. Patients with persistently elevated fasting serum triglyceride levels of 500 mg/dL or more who do not respond to dietary intervention should be treated with gemfibrozil (600 mg twice daily prior to the morning and evening meals).

Indinavir

The standard dose of indinavir is 800 mg orally three times a day, although it is usually dosed twice daily in combination with ritonavir. Nausea and headache are common complaints with this drug. Indinavir crystals are present in the urine in approximately 40% of patients; this results in clinically apparent nephrolithiasis in about 15% of patients receiving indinavir. Lower urinary tract symptoms and acute kidney injury also have been reported. Patients taking this drug should be instructed to drink at least 48 ounces of fluid a day to ensure adequate hydration in an attempt to limit these complications. Mild indirect hyperbilirubinemia is also commonly observed in patients taking indinavir but is not an indication for discontinuation of the drug.

Saquinavir

Saquinavir is formulated only as a hard-gel capsule (Invirase). It should only be used with ritonavir (1000 mg of hard-gel saquinavir with 100 mg of ritonavir orally twice daily). The soft-gel capsule (Fortovase) has been removed from the market in the United States. The most common side effects with saquinavir are diarrhea, nausea, dyspepsia, and abdominal pain.

Ritonavir

Use of this potent PI at full dose (600 mg orally twice daily) has been limited by its inhibition of the cytochrome P450 pathway causing a large number of drug–drug interactions and by its frequent side effects of fatigue, nausea, and paresthesias. However, it is widely used in lower dose (eg, 100 mg daily to 100 mg twice daily) as a booster of other PIs.

Nelfinavir

Nelfinavir is the only PI for which ritonavir boosting is not recommended. Unboosted nelfinavir is generally not as potent as a boosted PI regimen (eg, lopinavir plus ritonavir). The dose of nelfinavir is 1250 mg orally twice daily. Diarrhea is a side effect in 25% of patients taking nelfinavir, but this symptom may be controlled with over-the-counter antidiarrheal agents in most patients.

Amprenavir

Amprenavir has efficacy and side effects similar to those of other PIs. Common side effects are nausea, vomiting, diarrhea, rash, and perioral paresthesia. The dose is 1200 mg orally twice daily. The concentration of amprenavir decreases when coadministered with ethinyl estradiol; therefore, amprenavir should be used with circumspection in the treatment of transgender persons requiring high-dose estrogen.

Fosamprenavir

Fosamprenavir is a prodrug of amprenavir. Its major advantage over using amprenavir is a much lower pill burden. For PI-naïve patients, it can be dosed at 1400 mg orally twice daily (four capsules a day) or at 1400 mg orally daily (two capsules) with ritonavir 200 mg orally daily (two capsules) or at 700 mg orally with ritonavir 100 mg orally twice daily. Patients previously treated with PIs should receive 700 mg orally with ritonavir 100 mg orally twice daily. Side effects are similar to those with amprenavir—most commonly gastrointestinal distress and hyperlipidemia. As with amprenavir, the concentration of fosamprenavir decreases when coadministered with ethinyl estradiol; therefore, fosamprenavir should be used with circumspection in the treatment of transgender persons requiring high-dose estrogen.

Lopinavir/r

Lopinavir/r is lopinavir (200 mg) coformulated with a low dose of ritonavir (50 mg) to maximize the bioavailability of lopinavir. It has been shown to be more effective than nelfinavir when used in combination with stavudine and lamivudine. The usual dose is 400 mg lopinavir with 100 mg of ritonavir (two tablets) orally twice daily with food. When given along with efavirenz or nevirapine, a higher dose (600 mg/150 mg—three tablets) is usually prescribed. The most common side effect is diarrhea, and lipid abnormalities are frequent.

Atazanavir

Atazanavir can be dosed only once daily (two 200-mg capsules with food) or 300 mg in combination with 100 mg of ritonavir once daily). When used without ritonavir, it has only minimal or no impact on cholesterol and triglyceride levels. The most common side effect is mild hyperbilirubinemia that resolves with discontinuation of the drug. Both tenofovir and efavirenz lower the serum concentration of atazanavir. Therefore, when either of these two drugs is used with atazanavir, it should be boosted by administering ritonavir. Proton pump inhibitors are contraindicated in patients taking atazanavir because atazanavir requires an acidic pH to remain in solution.

Tipranavir

Tipranavir is the only nonpeptidic PI currently approved by the US Food and Drug Administration (FDA). Because of its unique structure, it is active against some strains of HIV that are resistant to other PIs. It is dosed with ritonavir (two 250 mg capsules of tipranavir with two 100 mg capsules of ritonavir orally twice daily with food). The most common side effects are nausea, vomiting, diarrhea, fatigue, and headache. Tipranavir/ritonavir has been also associated with liver damage and should be used very cautiously in patients with underlying liver disease. Recent reports of intracranial hemorrhage in patients taking tipranavir-containing regimens have raised additional safety concerns about this potent PI. Because it is a sulfa-containing drug, its use should be closely monitored in patients with sulfa allergy.

Darunavir

Darunavir is the most recently approved PI with impressive antiviral activity in the setting of significant PI resistance and in treatment-naïve patients. Darunavir has been added to the list of recommended PIs for initial treatment of HIV where it can be dosed daily (darunavir, 800 mg, with ritonavir, 100 mg). Darunavir, 600 mg orally twice daily, with ritonavir, 100 mg orally twice daily, is recommended for patients with prior PI treatment experience or PI resistance. Darunavir appears to be reasonably well tolerated with a safety profile similar to other PIs, such as lopinavir/ritonavir. Like tipranavir, darunavir is a sulfa-containing drug, and its use should be closely monitored in patients with sulfa allergy.

Nonnucleoside Reverse Transcriptase Inhibitors

NNRTIs inhibit reverse transcriptase at a site different from that of the nucleoside and nucleotide agents described above. All four NNRTIs have shown antiviral activity as measured by HIV viral load and CD4 responses. The major advantage of the NNRTIs is that two of them (nevirapine and efavirenz) have potencies comparable to that of PIs—with lower pill burden and fewer side effects. In particular, they do not appear to cause lipodystrophy; patients with cholesterol and triglyceride elevations who are switched from a PI to an NNRTI may have improvement in their lipids. The resistance patterns of the NNRTIs are distinct from those of the PIs, so their use still leaves open the option for future PI use.

The NNRTIs can be used with PIs in patients who are difficult to suppress on simpler regimens or when it is difficult to identify at least two nucleoside/nucleotide agents to which the patient is not resistant. Because these agents may cause alterations in the clearance of PIs, dose modifications may be necessary when these two classes of medications are administered concomitantly. There is a high degree of cross- resistance between the "first generation" NNRTIs, such that resistance to one drug in this class uniformly predicts resistance to other drugs. However, etravirine has been approved as a "second-generation" NNRTI and appears to have consistent antiviral activity in patients with prior exposure and resistance to the "first generation" drugs of this class. In particular, the K103N mutation, which is associated with a high level of resistance to nevirapine, efavirenz, and delavirdine, does not appear to have an impact on etravirine. There is no therapeutic reason for using more than one NNRTI at the same time.

Efavirenz

The major advantage of efavirenz is that it can be given once daily in a single dose (600 mg orally). The side effects are neurologic, with patients reporting symptoms ranging from lack of concentration and strange dreams to delusions and mania. Fortunately, the neurologic side effects of efavirenz subside over time, usually within a month. Administration of efavirenz with food, especially fatty food, may increase its serum levels and consequent neurotoxicity. Due to teratogenicity, efavirenz should be avoided in women who wish to conceive or are already pregnant. A once-daily fixed- dose combination of efavirenz, tenofovir, and emtricitabine in a single pill (Atripla) is available and is probably the best first choice for treatment-naïve patients without significant drug resistance.

Nevirapine

The target dose of nevirapine is 200 mg orally twice daily, but it is initiated at a dose of 200 mg once a day to decrease the incidence of rash, which is as high as 40% when full doses are begun immediately. If rash develops while the patient is taking 200 mg a day, liver enzymes should be checked and the dose should not be increased until the rash resolves. Patients with mild rash and no evidence of hepatotoxicity can continue to be treated with nevirapine. Nevirapine should not be used in treatment-naïve women with high CD4 counts (> 250/mcL). Because of potential fatal hepatotoxicity, nevirapine should only be used in patients who cannot tolerate efavirenz.

Delavirdine

Of the available "first generation" NNRTIs, delavirdine is used the least largely because of its less convenient dosing and pill burden compared with the other available NNRTIs. Unlike nevirapine and efavirenz, delavirdine inhibits P450 cytochromes rather than inducing these enzymes. This means that delavirdine can act like ritonavir and boost other antiretrovirals, although delavirdine is not as potent as ritonavir in this capacity. The dosage is 400 mg orally three times a day. The major side effect is rash.

Etravirine

Etravirine is the most recently approved NNRTI for the treatment of patients with prior NNRTI intolerance or resistance. The DUET trials demonstrated potent and durable antiviral activity in patients with NNRTI resistance to "first-generation" NNRTIs. Etravirine dosage is two 100-mg tablets twice daily. It should be used with a PI and a nucleoside/nucleotide analog and not just with two nucleoside/nucleotide analogs. The most common side effects are rash and nausea. Prior rash due to treatment with one of the other NNRTIs does not make rash more likely with etravirine.

Entry Inhibitors

Enfuvirtide

Enfuvirtide (Fuzeon) is known as a fusion inhibitor; it blocks the entry of HIV into cells by blocking the fusion of the HIV envelope to the cell membrane. The addition of enfuvirtide to an optimized antiretroviral regimen improved CD4 counts and lowered viral loads in heavily pretreated patients with multidrug-resistant HIV. Unfortunately, resistance develops rapidly in patients receiving nonsuppressive treatment. The dose is 90 mg by subcutaneous injection twice daily; unfortunately, painful injection site reactions develop in most patients.

Maraviroc

Maraviroc is the first CCR5 co-receptor antagonist to be approved for use. Drugs in this class work by preventing the virus from entering uninfected cells by blocking the CCR5 co-receptor. Unfortunately, this class of entry inhibitors is only active against "CCR5-tropic virus." This form of the HIV-1 virus tends to predominate early in infection, while so-called "dual/mixed tropic virus" (which utilizes either R5 or CXCR4 co-receptors) emerges later as infection progresses. Approximately 50–60% of previously treated HIV-infected patients have circulating CCR5-tropic HIV. The drug has been shown to be effective in HIV-infected persons with ongoing viral replication despite being heavily treated and who have CCR5-tropic virus. Tropism testing should be performed before beginning the medication. The dose of maraviroc is 150–300 mg orally twice daily, based on the other drugs the patient is taking at the time. Common side effects are cough, fever, rash, musculoskeletal problems, abdominal pain, and dizziness.

Integrase inhibitors

Raltegravir

Raltegravir is the first HIV integrase inhibitor to be approved by the FDA. Integrase inhibitors slow HIV replication by blocking the HIV integrase enzyme needed for the virus to multiply. Raltegravir was impressively effective (when combined with other active drugs) in the treatment of HIV-infected patients with documented resistance to at least one drug in each of the three main classes of antiretroviral medications (nucleoside analogs, PIs, NNRTIs). Clinical trials of integrase inhibitors reveal a consistent pattern of more rapid decline in viral load compared with more standard PI/r or NNRTI-based regimens. The clinical significance of this observation is yet to be defined. Despite the impressive antiviral potency of this new exciting class of antiretroviral drugs, it appears that high-level resistance to integrase inhibitors emerges quickly in the setting of virologic failure (much like with the NNRTIs). Therefore, it is critical that raltegravir be used in combination with other active antiretroviral agents.

Recent studies in treatment-naïve patients have demonstrated that raltegravir in combination with TDF/FTC is as effective as the current first-line choice of EFV/TDF/FTC for daily treatment and has fewer side effects. Furthermore, the CD4 response appeared better in patients treated with the raltegravir combination. These results led to FDA approval for raltegravir in treatment-naïve patients. The dose of raltegravir is 400 mg orally twice daily. Common side effects are diarrhea, nausea, and headache.

Elvitegravir

Elvitegravir is another integrase inhibitor that is in phase 3 studies. The dose is 125 mg once daily, given with ritonavir (100 mg) for boosting. Elvitegravir showed impressive short-term virologic responses in phase 2 studies.

Constructing Regimens

There is now little debate about the necessity for combining drugs to achieve long-term suppression of HIV and its associated clinical benefit. Only combinations of three or more drugs have been able to decrease HIV viral load by 2–3 logs and allow long-term suppression of HIV RNA to below the threshold of detection.

Current evidence supports the use of Truvada (tenofovir and emtricitabine) as the "nucleoside/nucleotide backbone" combined with efavirenz as the initial regimen. This regimen has been shown to be more effective and better tolerated than Combivir (zidovudine and lamivudine) and Epzicom (abacavir/lamivudine). It has the advantages of once daily dosing and is available as a single pill (Atripla). Because 8–10% of newly infected persons in some urban areas of the United States have NNRTI resistance, resistance testing should be performed before initiating efavirenz in this population. Regimens that include only nucleoside and nucleotide analogs without nonnucleoside agents or PIs are clinically inferior and should only be used for patients that cannot adhere to a more complicated regimen.

In the absence of head-to-head comparisons of different regimens in different situations, several general principles should guide the choice of combinations. The most important determinant of treatment efficacy is adherence to the regimen. Therefore, it is vitally important that the regimen chosen be one to which the patient can easily adhere. In general, patients are more compliant with medication regimens that are once or twice a day only, do not require special timing with regard to meals, can be taken at the same time as other medications, do not require refrigeration or special preparation, and do not have bothersome side effects. To the extent possible, agents to which the patient has not been exposed are preferable to drugs for which resistance mutations may have already occurred. Toxicities should ideally be nonoverlapping. An individual's relative contraindications to a given drug or drugs should be considered. The regimen should not include agents that are either virologically antagonistic or incompatible in terms of drug–drug interactions. For example, etravirine should not be used with boosted tipranavir because of drug-drug interactions. Compatible dosing schedules—prescribing medications that can be taken at the same time—improve adherence to treatment. Finally, highly complex therapeutic regimens should be reserved for individuals who are capable of adhering to the rigorous demands of taking multiple medications and having this therapy closely monitored. Conversely, simplified regimens that deliver the lowest number of pills given at the longest possible dosing intervals are desirable for patients who have difficulty taking multiple medications.

Possible ways of incorporating nonnucleoside agents and protease inhibitors into combinations are displayed in

Figure 31–2.

Figure 31–2
Approach to initial and subesequent antiretroviral therapy.

A number of points about the "nucleoside/nucleotide backbone" of regimens have become clearer. The combination of stavudine plus didanosine should be avoided, since there is increased risk of toxicities, in particular in pregnant women because of the increased risk of lactic acidosis, which can be fatal. Moreover, the nucleoside pair of zidovudine and stavudine should be avoided because of increased toxicity and the potential for antagonism that results from intracellular competition for phosphorylation. Finally, the combination of didanosine with tenofovir should be avoided due to observed declines in CD4 counts.

In choosing which agents to include in an initial antiretroviral regimen, ease of administration, minimization of side effects, drug resistance pattern, and future treatment options should all be considered. In designing second-line regimens for patients with resistance to initial therapy, the goal is to identify three drugs from at least two different classes to which the virus is not resistant. This can be quite complicated because of the problem of cross-resistance between drugs within a class. For example, the resistance patterns of lopinavir/ritonavir and indinavir are overlapping, and patients with virus resistant to these agents are unlikely to respond to nelfinavir or saquinavir even though they have never received treatment with these agents. Similarly, the resistance patterns of nevirapine and efavirenz are overlapping. With several new classes of drugs and new generations of existing drug classes now available, the ability to provide fully suppressive regimens even to patients with extensive treatment experience and drug resistance has become more realistic. The goal of therapy, therefore, should be to fully suppress viral loads to < 50 copies/mL even for highly treatment-experienced patients.

In addition to taking a careful history of what antiretroviral agents a patient has taken and for how long, genotypic and phenotypic resistance testing can provide useful information in designing second-line regimens (see below).

Whatever regimen is chosen, patients should be coached in ways to improve adherence. For certain populations (eg, unstably housed individuals), specially tailored programs that include drug dispensing are needed.

For some patients, it is impossible to construct a tolerable regimen that fully suppresses HIV. In such cases, clinicians and patients should consider their goals. Patients maintained on effective antiretroviral agents often benefit from these regimens (eg, higher CD4 counts, fewer opportunistic infections) even if their virus is detectable. In some cases, patients may request a drug holiday during which they are taken off all medications. Patients often immediately feel better because of the absence of drug side effects. Unfortunately, structured treatment interruptions generally result in viral rebound and CD4 decline, and patients who interrupt their treatment fare poorly compared with patients who continue their regimens without interruption.

The Challenge of Drug Resistance

HIV-1 drug resistance limits the ability to fully control HIV replication and is a leading cause for antiretroviral regimen failure. Resistance has been documented for all currently available antiretrovirals including the new classes of fusion inhibitors, CCR5 inhibitors, and integrase inhibitors. The problem of drug resistance is widespread in HIV-infected patients undergoing treatment in countries where ART is widely available. A cohort study revealed that some degree of resistance developed over the first 30 months of therapy in nearly one-third of patients starting a HAART regimen. Patients who have taken various antiretroviral regimens and who now have resistant HIV-1 represent a major challenge for the treating clinician. Resistance is now also documented in patients who are ART-naive, but who have been infected with a drug resistant strain—"primary resistance." Cohort studies of antiretroviral treatment–naive patients entering care in North America and Western Europe show that roughly 10–12% (and as high as 25%) of recently infected individuals have been infected with a drug-resistant strain of HIV-1.

Current expert guidelines recommend resistance testing as part of standard baseline testing in all patients. Resistance testing is also recommended for patients who are on an antiretroviral regimen and have suboptimal viral suppression (ie, viral loads > 1000 copies/mL). Both genotypic and phenotypic tests are commercially available and in randomized controlled studies their use has been shown to result in improved short-term virologic outcomes compared to making treatment choices without resistance testing. Furthermore, multiple retrospective studies have conclusively demonstrated that resistance tests provide prognostic information about virologic response to newly initiated therapy that cannot be gleaned from standard clinical information (ie, treatment history, examination, CD4 count, and viral load tests).

Because of the complexity of resistance tests, many clinicians require expert interpretation of results. In the case of genotypic assays, results may show that the mutations that are selected for during ART are drug-specific or contribute to broad cross-resistance to multiple drugs within a therapeutic class. An example of a drug-specific mutation for the reverse transcriptase inhibitors would be the M184V mutation that is selected for by lamivudine or emtricitabine therapy—this mutation causes resistance only to those two drugs. Conversely, the thymidine analog mutations ("TAMs") of M41L, D67N, K70R, L210W, T215Y/F, and T219Q/K/E are selected for by either zidovudine or stavudine therapy, but cause resistance to all the drugs in the class and often extend to the nucleotide inhibitor tenofovir when three or more of these TAMs are present. Further complicating the interpretation of genotypic tests is the fact that some mutations that cause resistance to one drug can actually make the virus that contains this mutation more sensitive to another drug. The M184V mutation, for example, is associated with increased sensitivity to zidovudine, stavudine, and tenofovir. The most common mutations associated with drug resistance and cross-resistance patterns for NRTIs, NNRTIs, and PIs can be found at http://hivdb.stanford.edu (see eFigure 31-2.1: illustration), (see eFigure 31-2.2: illustration), (see eFigure 31-2.3: illustration). Phenotypic tests also require interpretation in that the distinction between a resistant virus and sensitive one is not fully defined for all available drugs.

eFigure 31-2.1

Most common mutations associated with drug resistance and cross-resistance with nucleotide reverse transcriptase inhibitors. AZT, zidovudine; d4T, stavudine; TDF, tenofovir; ABC, abacavir; ddI, didanosine; 3TC, lamivudine; FTC, emtricitabine.

Both methods of resistance testing are limited by the fact that they may measure resistance in only some of the viral strains present in an individual. Resistance results may also be misleading if a patient is not taking antiretroviral medications at the time of testing. Thus, resistance results must be viewed cumulatively—ie, if resistance is reported to an agent on one test, it should be presumed to be present thereafter even if subsequent tests do not give the same result.

Course & Prognosis

With improvements in therapy, patients are living longer after the diagnosis of AIDS. A population-based study conducted in Denmark found that HIV-infected persons at age 25 years without hepatitis C had a life expectancy of 39 additional years. Unfortunately, not all HIV-infected persons have access to treatment. Studies consistently show less access to treatment for blacks, the homeless, and injection drug users. In addition to access to treatment, sustaining lower mortality will require developing new treatments for patients in whom resistance to existing agents develops. For patients whose disease progresses even though they are receiving appropriate treatment, meticulous palliative care must be provided (see Chapter 5: Palliative Care & Pain Management), with attention to pain control, spiritual needs, and family (biologic and chosen) dynamics.

When to Refer

- Clinicians with limited experience in HIV/AIDS should refer HIV-infected patients to specialists with experience, given the increasing number and complexity of treatment regimens available.
- Extra efforts should be made to obtain specialty consultation for those patients with detectable viral loads on ART; those intolerant of standard medications; those in need of systemic chemotherapy; and those with complicated opportunistic infections, particularly when invasive procedures or experimental therapies are needed.

When to Admit

Patients with opportunistic infections who are acutely ill (eg, who are febrile, who have had rapid change of mental status, or who are in respiratory distress) or who require intravenous medications.

Human Herpesviruses: Introduction

Herpesviruses cause a wide spectrum of human disease. Eight identified human herpesviruses (HHV) include herpes simplex virus (HSV) (type 1), HSV (type 2), varicella zoster virus (VZV) (type 3), Epstein–Barr infectious mononucleosis virus (type 4), and cytomegalovirus (CMV) (type 5). A sixth type (HHV-6) has been identified as a causative agent of roseola (exanthema subitum), and a seventh (HHV-7) is serologically associated with several syndromes. Another herpesvirus (HHV-8) is linked with Kaposi sarcoma (see Chapter 31: HIV Infection & AIDS).

Subclinical primary infection with the herpesviruses is more common than clinically manifest illness. Each persists in a latent state for the remainder of the person's life. With HSV and VZV, virus remains latent in sensory ganglia; upon reactivation, lesions appear in the distal sensory nerve distribution. As a result of disease-, drug-, or radiation-induced immunosuppression, virus reactivation may lead to widespread lesions in affected organs such as the viscera or the central nervous system (CNS). Severe or fatal illness may occur in infants and immunodeficient persons. Herpesviruses can transform cells in tissue culture. Associations with malignancies include Epstein–Barr virus (EBV) with Burkitt lymphoma and nasopharyngeal carcinoma and HHV-8 with primary effusion lymphoma and Kaposi sarcoma.

Herpesviruses 1 & 2

Essentials of Diagnosis

- Spectrum of illness from stomatitis and urogenital lesions to facial nerve paralysis (Bell palsy) and encephalitis.
- Variable intervals between exposure and clinical disease, since HSV causes both primary (which may be subclinical) and reactivation disease.
- Successful management with acyclovir or related acyclic compounds (valacyclovir, famciclovir).

General Considerations

Herpesviruses 1 and 2 affect primarily the oral and genital areas, respectively. Seroprevalence to both viruses increases with age; seroprevalence to HSV-2 increases with sexual activity. Disease is typically a manifestation of reactivation. Although HSV-2 is the most common cause of genital ulcers in the developed world, HSV-1 is increasingly recognized as causing primary urogenital infections. Genital recurrences are much more frequent with HSV-2 and gradually decrease over time, whereas HSV-1 recurrences are rare after the first year. Risk factors for HSV transmission include black race, female gender, a history of sexually transmitted infections (STIs), an increased number of partners, contact with commercial sex workers, lower socioeconomic status, young age of onset of sexual activity, and total duration of sexual activity. Asymptomatic shedding of either virus is common, especially following primary infection or symptomatic recurrences, and may be responsible for transmission. HSV-2 increases the risk of HIV acquisition, and in advanced HIV infection, HSV reactivates more frequently. HIV replication is increased by interaction with HSV proteins; suppression of HSV-2 can decrease genital tract shedding of HIV as well as plasma HIV RNA levels.

Clinical Findings

Symptoms and Signs

Mucocutaneous disease

HSV-1 mucocutaneous disease largely involves the mouth and oral cavity ("herpes labialis" or "gingivostomatitis;" the latter largely in children). Digital lesions (**whitlows**) are an occupational hazard in medicine, nursing, and dentistry (Plate 94). Certain contact sports (eg, wrestling) are associated with outbreaks of skin infections ("herpes gladiatorum"). Asymptomatic shedding of HSV-1 is frequent, with most infected individuals shedding virus at least once a month.

Plate 94.

Herpetic whitlow. (Used, with permission, from Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H, Tysinger J. *The Color Atlas of Family Medicine*. McGraw-Hill, 2009.)

Vesicles form moist ulcers after several days and epithelialize over 1–2 weeks if untreated (see photograph); (see photograph). Primary infection is usually more severe than recurrences but may be asymptomatic. Recurrences often involve fewer lesions, tend to be labial, heal faster, and are induced by stress, fever, infection, sunlight, chemotherapy (eg, fludarabine), or other undetermined factors.

HSV-2 lesions largely involve the genital tract. Virus remains latent in presacral ganglia. Lesions arising on the external genitalia are multiple, painful, small, grouped, and vesicular. Occasionally, lesions arise in the perianal region or on the buttocks and upper thighs. Dysuria, cervicitis, and urinary retention may occur in women.

Proctitis and sacral lesions in HIV-infected persons with CD4 cytopenia may present with extensive, ulcerating, weeping lesions. Large ulcerations and atypical lesions suggest drug-resistant isolates (see below).

Ocular disease

HSV can cause keratitis, blepharitis, and keratoconjunctivitis. Keratitis is usually unilateral, often with impaired visual acuity. Lesions limited to the epithelium usually heal without affecting vision, whereas stromal involvement can cause uveitis, scarring, and eventually blindness. Recurrences are frequent. HSV is the second most common cause, after VZV, of acute retinal necrosis.

Neonatal and congenital infection

Both herpesviruses can infect the fetus and induce congenital malformations (organomegaly, bleeding, and CNS abnormalities). Neonatal transmission during delivery is more common than intrauterine infection. Maternal infection during the third trimester is associated with the highest risk of neonatal transmission; about 70% of these infections are asymptomatic or unrecognized. Invasive fetal monitoring and vacuum or forceps delivery can facilitate the risk of transmitting herpes.

Central nervous system disease

HSV-1 predominantly causes herpes simplex encephalitis, while HSV-1 and HSV-2 are both associated with benign recurrent lymphocytic (Mollaret) meningitis. Primary HSV-2 infection in women often presents as aseptic meningitis. HSV-1 and HSV-2 are increasingly recognized as a cause of mild, nonspecific neurologic symptoms.

Herpes simplex encephalitis presents with nonspecific symptoms: a flu-like prodrome, followed by headache, fever, behavioral and speech disturbances, and focal or generalized seizures. The temporal lobe is often involved. Untreated disease and presentation with coma carry a high mortality rate, with many survivors suffering neurologic sequelae. In children, nonspecific symptoms may complicate establishing a diagnosis.

Disseminated infection

Disseminated HSV infection occurs in the setting of immunosuppression, either primary or iatrogenic, or rarely with pregnancy. In disseminated disease, skin lesions are not always present. Disseminated skin lesions are a particular complication in patients with atopic eczema (eczema herpeticum) and burns.

Bell palsy

An association between HSV-1 and Bell palsy is established.

Esophagitis and proctitis

HSV-1 can cause esophagitis in those with AIDS and other immunocompromised patients. CMV esophagitis is distinguished by the size and depth of the lesion (smaller and deeper for HSV). HSV-1 is also postulated to activate mononuclear cells in the pathogenesis of achalasia. Proctitis often occurs mainly in men who have sex with men.

Erythema multiforme

Herpes simplex viruses remain, with drugs, the leading association with erythema multiforme and with the more severe, mucosally involved Stevens–Johnson syndrome.

Other

Rarely, HSV causes fulminant hepatitis. HSV lower respiratory tract infection is common in mechanically ventilated patients, but its clinical significance is unknown. HSV-1 is associated with *Helicobacter pylori*–negative upper gastrointestinal tract ulcers. An association between HSV-1 and endocardial inflammation in the pathogenesis of atrial myxoma is postulated.

Laboratory Findings

Mucocutaneous disease

Diagnosis is usually made clinically, but viral cultures of vesicular fluid or direct fluorescent antibody staining of scraped lesions remain the standard of diagnosis. Polymerase chain reaction (PCR) is a more sensitive diagnostic assay. The presence of intranuclear inclusion bodies and multinucleated giant cells on a Tzanck preparation or Calcofluor stain is supportive of a diagnosis of herpetic viral infection. Type-specific serologies are useful for counseling HIV-infected individuals; pregnant women; sexual partners of persons infected with HSV; and those with an uncertain clinical history, high-risk behavior, or increased number of sexual partners.

Ocular disease

Keratitis is diagnosed by branching (dendritic) ulcers that stain with fluorescein.

Encephalitis and recurrent meningitis

Cerebrospinal fluid pleocytosis is common, with roughly equal numbers of red cells. HSV DNA PCR of the cerebrospinal fluid is a rapid, sensitive, and specific tool for early diagnosis. Antibodies to HSV in cerebrospinal fluid can confirm the diagnosis but appear late in the course of the disease. Viral culture shows a sensitivity of only 10%. MRI scanning is often a useful adjunct showing increased signal in the temporal and frontal lobes. Temporal lobe seizure foci may be demonstrated on electroencephalograms (EEGs).

Esophagitis and proctitis

Esophagitis is diagnosed by endoscopic biopsy and cultures. Proctitis may be diagnosed by rectal swab for PCR or culture, or both, although complicated cases may require biopsy.

Prevention

Besides antiviral suppressive therapy, prevention also requires counseling and the use of barrier precautions during sexual activity. Disclosure of partner status is associated with about a 50% reduction in the HSV-2 acquisition. Arguments favoring partner testing include confirming exposure, assistance with management, reducing the risk of transmission, and aiding in public health strategies.

Preventing spread to hospital staff and other patients from cases with mucocutaneous, disseminated, or genital disease requires isolation and the usage of handwashing and gloving–gowning precautions. Staff with active lesions (eg, whitlows) should not have contact with patients. Asymptomatic transmission occurs, especially with HSV-2. An HSV-2 glycoprotein-D vaccine under development appears to prevent infection and disease among women who are seronegative at baseline.

Treatment & Prophylaxis

Drugs that inhibit replication of HSV-1 and HSV-2 include trifluridine and vidarabine (both for keratitis), acyclovir and related compounds, foscarnet, and cidofovir (Table 32–1).

Table 32–1. Agents for viral infections.[1]

Drug	**Dosing**	**Spectrum**	**Renal Clearance/ Hemodialysis**	**CNS/CSF Penetration**	**Toxicities**
Acyclovir	200–800 mg orally five times daily; 250–500 mg/m^2 intravenously every 8 hours for 7 days	HSV, VZV	Yes/Yes	Yes	Neurotoxic reactions, reversible renal dysfunction, local reactions

Adefovir	10 mg daily orally	HBV	Yes/Yes	NA	Gastrointestinal symptoms, transaminitis, lactic acidosis, nephrotoxicity
Cidofovir	5 mg/kg intravenously weekly for 2 weeks, then every other week	CMV	Yes/NA	NA	Neutropenia, renal failure, ocular hypotonia
Entecavir	0.5 mg orally daily, increase to 1 mg orally daily in lamivudi	HBV	Yes/NA	NA	Lactic acidosis, rare exacerbation of HBV infection

	ne-resistant patients				
Famciclovir	500 mg orally three times daily for 7 days for acute VZV; 250 mg three times daily for 7–10 days for genital or cutaneous HSV-1/HSV-2 infection; 125 mg twice daily for 5 days for	HSV, VZV	Yes/NA	NA	NA

	recurrences (500 mg twice daily for 7 days if HIV-infected)				
Fomivirsen	165 mcg by intravitreal injection once weekly for 3 weeks, then every other week	CMV	NA	NA	Ocular inflammation, retinal detachment
Foscarnet	20 mg/kg intravenous bolus, then 120 mg/kg intravenously	CMV, HSV resistant to acyclovir, VZV,	Yes/Yes	Variable	Nephrotoxicity, genital ulcerations, calcium disturbances

	every 8 hours for 2 weeks; maintain with 60 mg/kg/d intravenously for 5 days each week	HIV-1			
Ganciclovir	5 mg/kg intravenous bolus every 12 hours for 14–21 days; maintain with 3.75 mg/kg/d intravenously for 5 days each week	CMV	Yes/Yes	Yes	Neutropenia, thrombocytopenia, CNS side effects
Idoxuridine	Topical, 0.1% every 1–	HSV keratitis	—	—	Local reactions

	2 hours for 3–5 days				
Interferon -2b	3–5 million international units subcutaneously three times weekly to daily. Intralesionally: 1 million international units per 0.1 mL in up to five warts three times weekly for 3 weeks	HBV, HCV, HPV	Yes/Yes	—	Influenza-like syndrome, myelosuppression, neurotoxicity

Interferon -n3	0.05 mL/wart biweekly up to 8 weeks	HPV	NA/NA	NA	Local reactions
	3 mU intravenously three times per week	? HCV	NA/NA	NA	Influenza-like syndrome, myelosuppression, neurotoxicity
Lamivudine (3TC)	12 mg/kg/d	HIV-1, ?HIV-2, HBV	Yes/NA	Yes	Skin rash, headache, insomnia
Oseltamivir	75 mg twice daily for 5 days beginning 48 hours after onset of symptom	Influenza A and B	Yes/NA	NA	Few

	s				
Penciclovir	Topical, 1% cream every 2 hours for 4 days	HSV	No/No	No	Local reactions
Palivizumab	15 mg/kg intramuscularly every month in RSV season	RSV	No/No	No	Upper respiratory infection symptoms
Ribavirin	Aerosol: 1.1 g/d as 20 mg/mL dilution over 12–18 hours for 3–7 days (See text for Lassa fever doses.)	RSV, severe influenza A or B, Lassa fever	Yes/No	Yes	Wheezing

Trifluridine	Topical, 1% drops every 2 hours to 9 drops/d	HSV keratitis	—	—	Local reactions
Valacyclovir	1 g orally three times daily for 7 days for acute VZV; 1 g twice daily for primary genital HSV-1/HSV-2 infection with 500 mg three times daily for recurrences	VZV, HSV	Yes/Poorly	NA	Thrombotic thrombocytopenic purpura or hemolytic-uremic syndrome in AIDS
Valganciclovir	900 mg orally	CMV	Yes/Yes	Yes	See ganciclovir

	twice daily for 3 weeks; 900 mg daily as maintenance				
Vidarabine	15 mg/kg/d intravenously for 10 days	HSV, VZV	Yes/Yes	Yes	Teratogenic, megaloblastosis, neurotoxicity
Zanamivir	2–5 mg inhalations twice daily for 5 days	Influenza A and B	Yes/NA	NA	Few

[1] Agents used exclusively in the management of HIV infection and AIDS are found in Chapter 31: HIV Infection & AIDS.

CNS, central nervous system; CSF, cerebrospinal fluid; HSV, herpes simplex virus; VZV, varicella-zoster virus; HBV, hepatitis B virus; CMV, cytomegalovirus; HPV, human papillomavirus; HCV, hepatitis C virus; RSV, respiratory syncytial virus.

Mucocutaneous Disease

While treatment is often not necessary in immunocompetent patients, it can ameliorate and shorten the duration of symptoms if initiated early. For primary genital infection, oral agents are generally used and include acyclovir, 200 mg five times a day or 400 mg three times a day; valacyclovir, 1 g twice daily; or famciclovir, 250 mg three times daily; all given for 7–10 days. Most experience in treating primary herpes labialis is with acyclovir (same doses and duration as for genital infection). Intravenous acyclovir (5–10 mg/kg every 8 hours for 7–14 days) should be considered in immunosuppressed patients.

For recurrent genital disease, acyclovir, 800 mg three times daily for 2 days; valacyclovir, 500 mg twice daily for 3 days; or famciclovir, 1 g twice daily for 1 day all show efficacy in controlled trials. Patient-initiated therapy with short courses of antivirals at first symptoms of recurrence is a frequently used and favorable approach. For the treatment of recurrences of herpes labialis, lesions heal faster with topical penciclovir than with topical acyclovir. Docosanol cream offers modest benefit. Oral acyclovir (same doses as above for 5 days) is more effective than topical agents. Recent data promote short-course therapy with higher doses of antivirals (eg, valacyclovir, 2 g twice daily for 1 day, or famciclovir, 1.5 g single dose).

Atypical isolates, large ulcerations, new lesions, or poor response to therapy suggest acyclovir resistance, which often occurs in immunodeficient patients. Alternatives include high dose acyclovir (4–5 g), which is effective in treating proctitis in the HIV-positive population, or foscarnet (40–60 mg/kg intravenously every 8 hours), adjusting the dose interval in patients with kidney dysfunction. Cidofovir is used in rare cases of infection resistant to both acyclovir and foscarnet.

Patients with frequent recurrent genital infections may be given **secondary prophylaxis** with acyclovir, 400 mg twice a day; valacyclovir, 500–1000 mg once daily; or famciclovir, 250 mg twice a day. For herpes labialis, valacyclovir, 500 mg daily, is the best option. Sunscreen may be useful for recurrences associated with sunlight exposure. Advantages of suppressive therapy include a significant reduction in acquisition of disease among the HSV-2 discordant heterosexual partners. AIDS patients with a history of mucocutaneous disease should continue receiving suppressive therapy unless a sustained improvement of immune status occurs. Among the HIV-infected, the use of highly active antiretroviral therapy (HAART) is associated with fewer days of HSV-1 or -2 lesions.

Keratitis

For the treatment of acute epithelial keratitis, topical antivirals (ophthalmic trifluridine, vidarabine, acyclovir, and ganciclovir are all nearly equivalent in efficacy) are recommended. Combination of topical antivirals with interferon or debridement (or both) hastens healing. The usage of topical corticosteroids may exacerbate the infection, although systemic corticosteroids may help with selected cases of stromal infection. Long-term treatment (greater than 1 year) with acyclovir at a dosage of 800 mg/d orally decreases recurrence rates.

Neonatal Disease

Acyclovir intravenously is effective for disseminated lesions in neonatal disease. The dosage is 20 mg/kg intravenously every 8 hours for 14–21 days. Counseling with serologic screening should be offered to pregnant mothers. The use of maternal antenatal suppressive therapy with acyclovir (typically, 400 mg three times daily) beginning at 36 weeks gestation decreases the presence of detectable HSV, the rates of recurrence at delivery, and the need for cesarean section. Cesarean section is recommended for pregnant women with active genital lesions or typical prodromal symptoms.

Encephalitis

Because of the need for rapid treatment and the difficulties associated with brain biopsy, patients with suspected HSV encephalitis are given intravenous acyclovir (10 mg/kg every 8 hours for 10 days or more, adjusting for kidney dysfunction), starting upon suspicion of diagnosis, and stopping if another diagnosis is established. If the PCR is negative and clinical suspicion remains high in the absence of a biopsy, treatment should be continued for 10 days because the false-negative rate for PCR can be as high as 25% (especially in children) and acyclovir is relatively nontoxic. Long-term neurologic sequelae are common and late pediatric relapse is recognized.

Disseminated Disease

Disseminated disease responds best to parenteral acyclovir (see the preceding paragraph for dosages) when treatment is initiated early.

Bell Palsy

Prednisolone, 25 mg orally twice daily for 10 days started within 72 h of onset, significantly increases the rate of recovery. Valacyclovir (but not acyclovir), 1 g orally daily for 5 days, may be beneficial if started within 7 days of onset along with corticosteroid therapy.

Esophagitis and Proctitis

Patients with esophagitis should receive either intravenous acyclovir at a dosage of 5–10 mg/kg every 8 hours or oral acyclovir, 400 mg five times daily. Maintenance therapy for AIDS patients is acyclovir at a dosage of 400 mg three to five times daily. Proctitis is treated with similar dosages and usually responds within 5 days.

Erythema Multiforme

Suppressive therapy with oral acyclovir (400 mg twice a day for 6 months) decreases the recurrence rate of HSV-associated erythema multiforme. Valacyclovir (500 mg twice a day) may be effective in cases unresponsive to acyclovir.

Varicella (Chickenpox) & Herpes Zoster (Shingles)

Essentials of Diagnosis

- Exposure 14–21 days before onset.
- Fever and malaise just before or with eruption.
- Rash: pruritic, centrifugal, papular, changing to vesicular ("dewdrops on a rose petal"), pustular, and finally crusting.

General Considerations

Varicella zoster virus (VZV) is HHV-3. Disease manifestations include chickenpox (varicella) and shingles (herpes zoster). Chickenpox is generally a disease of the childhood. It has an incubation period of 10–20 days (average 2 weeks) and is highly contagious, spreading by inhalation of infective droplets or contact with lesions.

The incidence and severity of herpes zoster ("shingles") increases with age due to an age-related decline in immunity against VZV. More than half of all patients in whom herpes zoster develops are older than 60 years. The annual incidence of herpes zoster in the United States is at least 1 million cases, which is expected to increase as the mean population age increases.

Clinical Findings

Varicella

Symptoms and signs

(Table 32–2.) Fever and malaise are mild in children and more marked in adults. The pruritic rash begins prominently on the face, scalp, and trunk, and later involves the extremities. Maculopapules change in a few hours to vesicles that become pustular and eventually form crusts (Plates 95 and 96). New lesions may erupt for 1–5 days, so that different stages of the eruption are usually present simultaneously. The crusts slough in 7–14 days. The vesicles and pustules are superficial and elliptical, with slightly serrated borders. Pitted scars are frequent sequelae.

Table 32–2. Diagnostic features of some acute exanthems.

Disease	**Prodromal Signs and Symptoms**	**Nature of Eruption**	**Other Diagnostic Features**	**Laboratory Tests**
Eczema herpeticum	None.	Vesiculopustular lesions in		Herpes simplex virus

		area of eczema.		isolated in cell culture. Multinucleate giant cells in smear of lesion.
Varicella (chickenpox)	0–1 day of fever, anorexia, headache.	Rapid evolution of macules to papules, vesicles, crusts; all stages simultaneously present; lesions superficial, distribution centripetal.	Lesions on scalp and mucous membranes.	Specialized complement fixation and virus neutralization in cell culture. Fluorescent antibody test of smear of lesions.
Infectious	Fever,	Maculopa	Splenomeg	Atypical

mononucleosis (EBV)	adenopathy, sore throat.	pular rash resembling rubella, rarely papulovesicular.	aly, tonsillar exudate.	lymphocytes in blood smears; heterophil agglutination (Monospot test).
Exanthema subitum (HHV-6, 7; roseola)	3–4 days of high fever.	As fever falls by crisis, pink maculopapules appear on chest and trunk; fade in 1–3 days.		White blood count low.
Measles (rubeola)	3–4 days of fever, coryza, conjunctivitis, and cough.	Maculopapular, brick-red; begins on head and neck; spreads downwar	Koplik spots on buccal mucosa.	White blood count low. Virus isolation in cell culture. Antibody tests by hemagglutin

		d and outward, in 5–6 days rash brownish, desquamating. See atypical measles, below.		ation inhibition or neutralization.
Atypical measles	Same as measles.	Maculopapular centripetal rash, becoming confluent.	History of measles vaccination.	Measles antibody present in past, with titer rise during illness.
Rubella	Little or no prodrome.	Maculopapular, pink; begins on head and neck, spreads downward, fades in 3 days.	Lymphadenopathy, postauricular or occipital.	White blood count normal or low. Serologic tests for immunity and definitive diagnosis

		No desquamation.		(hemagglutination inhibition).
Erythema infectiosum (parvovirus B19)	None. Usually in epidemics.	Red, flushed cheeks; circumoral pallor; maculopapules on extremities.	"Slapped face" appearance.	White blood count normal.
Enterovirus infections	1–2 days of fever, malaise.	Maculopapular rash resembling rubella, rarely papulovesicular or petechial.	Aseptic meningitis.	Virus isolation from stool or cerebrospinal fluid; complement fixation titer rise.
Typhus	3–4 days of fever, chills, severe headach	Maculopapules, petechiae, initial distribution	Endemic area, lice.	Complement fixation.

	es.	centrifugal (trunk to extremities).		
Rocky Mountain spotted fever	3–4 days of fever, vomiting.	Maculopapules, petechiae, initial distribution centripetal (extremities to trunk, including palms).	History of tick bite.	Indirect fluorescent antibody; complement fixation.
Ehrlichiosis	Headache, malaise.	Rash in one-third, similar to Rocky Mountain spotted fever.	Pancytopenia, elevated liver function tests.	Polymerase chain reaction, immunofluorescent antibody.
Scarlet fever	One-half to 2 days of	Generalized, punctate,	Strawberry tongue, exudative	Group A -hemolytic streptococci

	malaise, sore throat, fever, vomiting.	red; prominent on neck, in axillae, groin, skin folds; circumoral pallor; fine desquamation involves hands and feet.	tonsillitis.	in cultures from throat; antistreptolysin O titer rise.
Meningococcemia	Hours of fever, vomiting.	Maculopapules, petechiae, purpura.	Meningeal signs, toxicity, shock.	Cultures of blood, cerebrospinal fluid. High white blood count.
Kawasaki disease	Fever, adenopathy, conjunctivitis.	Cracked lips, strawberry tongue, maculopapular	Edema of extremities. Angiitis of coronary arteries.	Thrombocytosis, electrocardiographic changes.

		polymorphous rash, peeling skin on fingers and toes.		
Smallpox (based on prior experience)	Fever, malaise, prostration.	Maculopapules to vesicles to pustules to scars (lesions develop at the same pace).	Centrifugal rash; fulminant sepsis in small percentage of patients, gastrointestinal and skin hemorrhages.	Contact CDC[1] for suspicious rash; EM and gel diffusion assays.

EBV, Epstein–Barr virus; EM, electron microscopy HHV, human herpesvirus.

Plate 95.

Primary varicella (chickenpox) skin lesions. (Public Health Image Library, CDC.)

Plate 96.

Chickenpox (varicella) with classic “dew-drop on rose petal” appearance. (Courtesy of Richard P. Usatine, MD; used, with permission, from Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H, Tysinger J. *The Color Atlas of Family Medicine*. McGraw-Hill, 2009.)

After the primary infection, the virus remains dormant in cranial nerves sensory ganglia and spinal dorsal root ganglia. Latent VZV will reactivate as herpes zoster in about 10–30% of persons (see below). Varicella is more severe in older patients and immunocompromised persons. In the latter, atypical presentations, including widespread dissemination in the absence of skin lesions, are often described.

Laboratory findings

Diagnosis is usually made clinically, with confirmation by direct immunofluorescent antibody (DFA) staining or PCR of scrapings from lesions. Multinucleated giant cells are usually apparent on a Tzanck smear or Calcofluor stain of material from the vesicle bases. Leukopenia and subclinical transaminase elevation are often present and thrombocytopenia occasionally occurs.

Herpes Zoster

Herpes zoster (**"shingles"**) usually occurs among adults, but cases are reported among infants and children. Skin lesions resemble those of chickenpox. Pain is often severe and commonly precedes the appearance of rash. Lesions follow a dermatomal distribution, with thoracic and lumbar roots being the most common. In most cases, a single unilateral dermatome is involved, but occasionally, neighboring and distant areas are involved. Lesions on the tip of the nose, inner corner of the eye, and root and side of the nose (Hutchinson sign) indicate involvement of the trigeminal nerve (herpes zoster ophthalmicus). Facial palsy, lesions of the external ear with or without tympanic membrane involvement, vertigo and tinnitus, and deafness signify geniculate ganglion involvement (Ramsay Hunt syndrome).

Complications

Varicella

Secondary bacterial skin superinfections, particularly with group A -hemolytic streptococci and *Staphylococcus aureus*, are the most common complications in children.

Cellulitis, erysipelas, and scarlet fever are described. Bullous impetigo and necrotizing fasciitis are less often seen. Other associations with varicella include epiglottitis, necrotizing pneumonia, osteomyelitis, septic arthritis, epidural abscess, meningitis, endocarditis, and purpura fulminans. Toxic shock syndrome can also occur.

Interstitial VZV pneumonia is more common in adults (especially smokers, HIV-infected patients, and pregnant women) and may result in acute respiratory distress syndrome (ARDS). After healing, numerous densely calcified lesions are seen throughout the lung fields on chest radiographs.

Cerebellar ataxia occurs among younger people at a frequency of 1:4000. A limited course and complete recovery are the rule. Encephalitis is infrequent (1:1000), occurs mostly in adults, and is characterized by delirium, seizures, and focal neurologic signs. Both mortality and long-term neurologic sequelae rates are about 10%. Ischemic strokes in the wake of acute VZV infection present a mean of 4 months after rashes and may be due to an associated vasculitis. Multifocal encephalitis, ventriculitis, myeloradiculitis, arterial aneurysm formation, and arteritis are also described in immunosuppressed persons.

Clinical hepatitis is uncommon and mostly presents in the immunosuppressed patient but can be fulminant and fatal.

Reye syndrome (fatty liver with encephalopathy) also complicates varicella (and other viral infections, especially influenza B), usually in childhood, and is associated with aspirin therapy (see Influenza, below).

When contracted during the first or second trimesters of pregnancy, varicella carries a very small risk of congenital malformations, including cicatricial lesions of an extremity, growth retardation, microphthalmia, cataracts, chorioretinitis, deafness, and cerebrocortical atrophy. If varicella develops around the time of delivery, the newborn is at risk for disseminated disease.

Herpes Zoster

Postherpetic neuralgia occurs in 60–70% of patients who have herpes zoster and are older than 60 years. The pain can be prolonged and debilitating. Risk factors for postherpetic neuralgia include age, female sex, prodrome, and severity of rash or pain.

Other less common complications include bacterial skin superinfections; herpes zoster ophthalmicus, which occurs with involvement of the trigeminal nerve and is a sight-threatening complication, especially when it involves the cornea or the iris; involvement of the geniculate ganglion of cranial nerve VII as well as cranial nerves V, VIII, IX, and X; aseptic meningitis; peripheral motor neuropathy; transverse myelitis; encephalitis; vasculopathy; acute retinal necrosis; and progressive outer retinal necrosis (largely among HIV infected persons). VZV is a major cause of Bell palsy in patients who are HSV seronegative. Diagnosis of neurologic complications requires the detection of VZV DNA or anti-VZV IgG in cerebrospinal fluid or the detection of VZV DNA in tissue. Zoster sine herpete (pain without rash) can also be associated with most of the above complications.

Prevention

Health care workers should be screened for varicella and vaccinated if seronegative. Patients with active varicella or herpes zoster are promptly separated from seronegative patients. For those with varicella, airborne and contact isolation is recommended, whereas for those with zoster, contact precautions are sufficient. For immunosuppressed patients with zoster, precautions should be the same as if the patient had varicella. Exposed serosusceptible patients should be placed in isolation and exposed serosusceptible employees should stay away from work between days 10 and 21 after exposure. Health care workers with zoster should receive antivirals during the first 72 hours of disease and withdraw from work until lesions are crusted. Postexposure prophylaxis should be evaluated (see below).

Varicella

Vaccination

Universal childhood vaccination against varicella is effective. A single antigen live attenuated vaccine (VARIVAX) or a quadrivalent measles, mumps, rubella, and varicella vaccine (ProQuad) are available. The first dose should be administered at 12–15 months of age and the second at 4–6 years. Aspirin should be avoided for at least 6 weeks because of the risk of Reye syndrome. This vaccine is safe, well tolerated, and is not associated with neurologic sequelae. Rashes, when secondary to the varicella vaccine, appear 15–42 days after vaccination.

For serosusceptible individuals older than 13 years, two doses of varicella vaccine (single antigen) administered 4 to 8 weeks apart is recommended. For those who received a single dose in the past, a catch-up second dose is advised. Household contacts of immunocompromised patients should adhere to these recommendations. Susceptible pregnant women need to receive the first dose of vaccine before discharge after delivery and the second dose 4–8 weeks later.

The vaccine, administered 3 months apart, should also be considered for HIV-infected children with age-specific $CD4^+$ T lymphocyte percentages of 15–24% and adolescents and adults with $CD4^+$ T lymphocyte counts 200 cells/mcL. The vaccine may also be given to patients with impaired humoral immunity or receiving corticosteroids at a dose < 2 mg/kg or a total of < 20 mg/d of prednisone. Persons who are receiving higher doses for over 2 weeks may be vaccinated after the corticosteroid therapy has been discontinued for over 1 month. Patients with leukemia, lymphoma, or other malignancies whose disease is in remission and who have not undergone chemotherapy for at least 3 months may be vaccinated, although the presence of both ancillary antiviral treatment and expert guidance are encouraged.

Postexposure

Postexposure vaccination is recommended for unvaccinated persons without other evidence of immunity. Varicella-zoster immune globulin (VZIG) (in short supply with production stopped in 2004) or VariZIG (a lyophilized product available under expanded access since December 2007) should be considered for susceptible exposed patients who cannot receive the vaccine, including immunosuppressed patients, neonates from mothers with varicella around the time of delivery, exposed premature infants born from serosusceptible mothers at > 28 weeks of gestation, neonates born at < 28 weeks of gestation regardless of maternal serostatus, and pregnant women. No controlled studies have evaluated the use of acyclovir in this setting. VZIG is given by intramuscular injection in a dosage of 12.5 units/kg up to a maximum of 625 units, with a repeat identical dose in 3 weeks if a high-risk patient remains exposed. VZIG has no place in therapy of established disease.

Further information may be obtained by calling the Centers for Disease Control and Prevention's Immunization Information Hotline (800-232-2522).

Herpes Zoster

A live attenuated VZV vaccine is available and should be offered to persons 60 years and older. In this population, the vaccine reduces the incidence of postherpetic neuralgia and herpes zoster by 67% and 51%, respectively.

Prophylaxis with acyclovir, 800 mg twice daily, can be considered in patients at high risk for reactivation (eg, allogeneic hematopoietic cell transplant patients).

Treatment

General Measures

In general, patients with varicella should be isolated until primary crusts have disappeared and kept at bed rest until afebrile. The skin is kept clean. Pruritus can be relieved with antihistamines, calamine lotion, and colloidal oatmeal baths. As an antipyretic, acetaminophen is used. Fingernails can be closely cropped to avoid skin excoriation and infection.

Antiviral Therapy

Acyclovir, 20 mg/kg (up to 800 mg per dose) orally four times daily for 5 days, should be given within the first 24 hours after the onset of rash and should be considered for patients older than 12 years, secondary household contacts (secondary cases tend to be more severe disease), patients with chronic cutaneous and cardiopulmonary diseases, and children receiving long-term therapy with salicylates (to decrease the risk of Reye syndrome). Experience with valacyclovir and famciclovir in these settings is scant.

In immunocompromised patients, in pregnant women during the third trimester, and in patients with extracutaneous disease (encephalitis, pneumonitis), antiviral therapy with high-dose acyclovir (30 mg/kg/d in three divided doses intravenously for at least 7 days) should be started once the diagnosis is suspected. Corticosteroids may be useful in the presence of pneumonia.

For uncomplicated herpes zoster, acyclovir (800 mg orally five times daily) or valacyclovir (1 g three times daily) for 7 days is recommended. Therapy should start within the first 72 hours of the onset of the lesions. Intravenous acyclovir is used for extradermatomal complications of zoster, although acyclovir is not fully effective in retinal disease. Foscarnet may be used for acyclovir-resistant VZV infections seen in immunosuppressed patients. The Ramsay Hunt syndrome is less responsive to antiviral therapy.

Treatment of Complications

Once established, postherpetic neuralgia may respond to gabapentin or lidocaine patches (FDA approved drugs for neuropathic pain). Tricyclic antidepressants, opioids, and capsaicin cream are also widely used and effective. The epidural injection of corticosteroids and local anesthetics appears to modestly reduce herpetic pain at 1 month but is not effective for prevention of long-term postherpetic neuralgia. Secondary bacterial infections are treated with antibiotics providing coverage for staphylococci.

Prognosis

The total duration of varicella from onset of symptoms to disappearance of crusts rarely exceeds 2 weeks. Fatalities are rare except in immunosuppressed patients.

Herpes zoster resolves in 2–6 weeks. Antibodies persist longer and at higher levels than with primary varicella. Eye involvement with herpes zoster necessitates periodic future examinations.

Epstein–Barr Virus & Infectious Mononucleosis

Essentials of Diagnosis

- Malaise, fever, and sore throat, sometimes with exudates.
- Palatal petechiae, lymphadenopathy, splenomegaly, and, occasionally, a maculopapular rash.
- Positive heterophil agglutination test (Monospot).
- Atypical large lymphocytes in blood smear;

lymphocytosis.
- Possible complications: hepatitis, myocarditis, neuropathy, encephalitis, airway obstruction secondary to lymph node enlargement, anti-i hemolytic anemia, thrombocytopenia.

General Considerations

Infectious mononucleosis is usually due to the EBV (HHV-4). More than 90% of adults worldwide are seropositive for EBV. Infectious mononucleosis may be seen at any age but usually occurs in the United States in persons between the ages of 10 and 35 years, sporadically or epidemically. In the developing world, infectious mononucleosis occurs at younger ages and tends to be less symptomatic. Rare cases in the elderly occur usually without the full symptomatology. EBV is largely transmitted by saliva but can also be recovered from genital secretions. Saliva may remain infectious during convalescence for 6 months or longer from symptom onset. The incubation period lasts several weeks.

Clinical Findings

Symptoms and Signs

The protean manifestations of infectious mononucleosis reflect the dissemination of the virus in the oral cavity and through peripheral blood lymphocytes and cell-free plasma (Plate 97). Fever, sore throat, fatigue, malaise, anorexia, and myalgia typically occur in the early phase of the illness. Physical findings include lymphadenopathy (discrete, nonsuppurative, slightly painful, especially along the posterior cervical chain) and splenomegaly (in up to 50% of patients). A maculopapular or occasionally petechial rash occurs in less than 15% of patients unless ampicillin has been given (when rash is seen in > 90%). Exudative pharyngitis, tonsillitis, or gingivitis may occur and soft palatal petechiae may be noted.

Plate 97.

Conjunctival hemorrhage of the eye due to infectious mononucleosis. (Courtesy of Dr. Thomas F. Sellers, Emory University, Public Health Image Library, CDC.)

Other manifestations include hepatitis, cholestasis, nervous system involvement (mononeuropathies and occasionally aseptic meningitis, encephalitis, optic neuritis, transverse myelitis, or Guillain–Barré syndrome), kidney disease (mostly interstitial nephritis), pneumonia, pleural involvement, and myocarditis. Airway obstruction from lymph node enlargement, pericarditis, life-threatening thrombocytopenia, severe CNS complications, and massive splenomegaly are all considered indications for hospitalization or close observation. Mesenteric adenitis may mimic acute abdomen.

Laboratory Findings

Initially infectious mononucleosis is associated with granulocytopenia followed within 1 week by a lymphocytic leukocytosis (> 50% of all leukocytes) with atypical lymphocytes (larger than normal mature lymphocytes, staining more darkly, and showing vacuolated, foamy cytoplasm and dark nuclear chromatin) comprising more than 10% of the leukocyte count. Hemolytic anemia, with anti-i antibodies, occurs occasionally as does thrombocytopenia (at times marked).

Heterophil (sheep cell agglutination) antibody tests and the correlated mononucleosis spot (Monospot) test usually become positive within 4 weeks after onset of illness and are specific but often not sensitive in early illness. During acute illness, there occurs a rise and fall in immunoglobulin M (IgM) antibody to EB virus capsid antigen (VCA) and a rise in IgG antibody to VCA, which persists for life. Antibodies (IgG) to EBV nuclear antigen (EBNA) appear after 4 weeks of onset and also persist. Absence of IgG and IgM VCA or the presence of IgG EBNA should make one reconsider the diagnosis of acute EBV infection. PCR for EBV DNA is useful in the evaluation of malignancies associated with EBV. For instance, detection of EBV DNA in cerebrospinal fluid shows a sensitivity of 90% and specificity of nearly 100%

for the diagnosis of primary CNS lymphoma in patients with AIDS. Monitoring of EBV DNA load in blood may be useful in early detection of posttransplant lymphoproliferative disorder in high-risk patients. PCR analysis may also be helpful in detecting primary infection and infectious mononucleosis in children, in narrowing the differential diagnosis of CNS processes, and in monitoring disease and treatment response in primary CNS lymphoma and posttransplant lymphoproliferative disorder. Detection of specific IgA antibodies is also being studied as a marker of primary infection in children. Hepatic aminotransferases and bilirubin are commonly elevated. In aseptic meningitis, the cerebrospinal fluid may show increased opening pressure, lymphocytosis with abnormal morphology, and increased protein concentration.

Differential Diagnosis

CMV infection, toxoplasmosis, acute HIV infection, secondary syphilis, HHV-6, rubella, and drug hypersensitivity reactions may be indistinguishable from infectious mononucleosis due to EBV, but exudative pharyngitis is usually absent and the heterophil antibody tests are negative. With acute HIV infection, rash and mucocutaneous ulceration are common but atypical lymphocytosis is much less common. Heterophil-negative infectious mononucleosis with nonsignificant lymphocytosis (especially if rash or mucocutaneous ulcers are present) should prompt investigation for acute HIV infection. Heterophil-negative infectious mononucleosis with atypical lymphocytosis can be caused by CMV, toxoplasmosis and, on occasion, EBV itself. Mycoplasmal infection may also present as pharyngitis, though lower respiratory symptoms usually predominate. A hypersensitivity syndrome induced by carbamazepine or phenytoin may mimic infectious mononucleosis.

The differential diagnosis of acute exudative pharyngitis includes diphtheria, gonococcal and streptococcal infections, and infections with adenovirus and herpes simplex. Head and neck soft tissue infections (pharyngeal and tonsillar abscesses) may occasionally be mistaken as the lymphadenopathy of mononucleosis.

Complications

Secondary bacterial pharyngitis can occur and is often streptococcal. Splenic rupture is a rare but dramatic complication, and a history of preceding trauma can be elicited in 50% of the cases. Acalculous cholecystitis, fulminant hepatitis with massive necrosis, pericarditis and myocarditis are also infrequent complications. Neurologic involvement—including transverse myelitis, encephalitis, and Guillain–Barré syndrome—is infrequent.

Treatment

General Measures

Over 95% of patients recover without specific antiviral therapy. Treatment is symptomatic with acetaminophen or other nonsteroidal anti-inflammatory drugs and warm saline throat irrigations or gargles three or four times daily. Acyclovir decreases viral shedding but has no clinical benefit. Corticosteroid therapy, although widespread, is not recommended in uncomplicated cases; its use is reserved for impending airway obstruction from enlarged lymph nodes, hemolytic anemia, and severe thrombocytopenia. The value of corticosteroid therapy in impending splenic rupture, pericarditis, myocarditis, and nervous system involvement is less well defined. If a throat culture grows -hemolytic streptococci, a 10-day course of penicillin or erythromycin is indicated. Ampicillin and amoxicillin are avoided because of the frequent association with rash.

Treatment of Complications

Hepatitis, myocarditis, and encephalitis are treated symptomatically. Rupture of the spleen requires splenectomy and is most often caused by deep palpation of the spleen or vigorous activity. Patients should avoid contact or collision sports for at least 4 weeks to decrease the risk of splenic rupture (even if splenomegaly is not detected by physical examination which can be insensitive).

Prognosis

In cases without complications, fever disappears in 10 days and lymphadenopathy and splenomegaly in 4 weeks. The debility sometimes lingers for 2–3 months.

Death is uncommon and is usually due to splenic rupture, hypersplenic phenomena (severe hemolytic anemia, thrombocytopenic purpura), or encephalitis.

Hurt C et al. Diagnostic evaluation of mononucleosis-like illnesses. Am J Med. 2007 Oct;120(10):911.e1–8. [PMID: 17904463]

Other Epstein–Barr Virus Syndromes

EBV viral antigens have been found in over 90% of patients with African Burkitt lymphoma or nasopharyngeal carcinoma (among whom quantified EBV DNA can be used to follow disease). A causative role for EBV has been postulated with both neoplasms. Chronic EBV infection is associated with aberrant cellular immunity (a low frequency of EBV-specific CD8 cells), an X-linked lymphoproliferative syndrome (Duncan disease), lymphomatoid granulomatosis, and a fatal T cell lymphoproliferative disorder in children. EBV is an important cause of hemophagocytic lymphohistiocytosis EBV-induced lymphoproliferation gives rise to B-cell lymphomas among immunodeficient patients, such as primary CNS lymphoma in HIV-infected individuals or posttransplant lymphoproliferative disorder in persons who have undergone transplantation. Rituximab (CD20 monoclonal antibody) is effective in treating some cases of posttransplant lymphoproliferative disorder and is often administered in conjunction with monitoring levels of EBV DNA load in the blood and, if indicated, CNS. Infusion of EBV-specific cytotoxic T cell lymphocytes (adoptive cell therapy) is also used but with a less established role.

Age is a major determinant of the type of tumor EBV causes, with T and NK cell tumors in childhood caused by chronic active EBV infections and peripheral T cell lymphomas and diffuse large B cell lymphomas in the elderly due to waning immunity. EBV is also associated with leiomyomas in children with AIDS and with nasal T cell lymphomas. There is no persuasive evidence that chronic fatigue syndrome is caused by EBV infection. Oral hairy leukoplakia and its association with EBV are discussed in Chapter 8: Ear, Nose, & Throat Disorders.

EBV is also implicated in the pathogenesis of a host of disorders from Hodgkin disease and gastric carcinoma to multiple sclerosis, chronic obstructive pulmonary disease (COPD), and rheumatic diseases.

When to Admit

- Acute meningitis, encephalitis, or acute Guillain-

Barré.
- Severe thrombocytopenia.
- Potential splenic rupture.
- Airway obstruction from severe adenitis.
- Significant hemolysis.
- Pericarditis.
- Abdominal findings mimicking an acute abdomen.

Cytomegalovirus Disease

Essentials of Diagnosis

- Mononucleosis-like syndrome.

- Frequent pathogen seen in transplant populations.
- Diverse clinical syndromes in HIV (retinitis, esophagitis, pneumonia, encephalitis).
- Major pathogen to consider in neonates in the differential of maternally transmitted agents.

General Considerations

Most CMV infections are asymptomatic. After primary infection, the virus remains latent in different cells including vascular endothelium, monocytes, macrophages, polymorphonuclear neutrophils, and renal and pulmonary epithelial cells. Seroprevalence in adults of Western developed countries is about 60–80% but is higher in developing countries. CMV seroprevalence increases with age, number of sexual partners, history of prior STIs, and low socioeconomic status. The virus can be isolated from a variety of tissues under nonpathogenic conditions. Transmission occurs through sexual contact, breastfeeding, blood products, or transplantation; it may also occur person-to-person (eg, day care centers) or be congenital. Serious disease occurs primarily in immunocompromised persons.

There are three recognizable clinical syndromes: (1) perinatal disease and CMV inclusion disease; (2) diseases in immunocompetent persons; and (3) diseases in immunocompromised persons. **Congenital CMV infection** is the most common congenital infection in developed countries (1% of all neonates). Transmission is much higher from mothers with primary disease than those with reactivation. About 10% of infected newborns will be symptomatic with CMV inclusion disease. In **immunocompetent persons** , acute CMV infection is the most common cause of mononucleosis-like syndrome with negative heterophil antibodies. CMV appears to play a role in critically ill immunocompetent adults wherein it is reactivated and associated with prolonged hospitalization and death. Other syndromes associated with CMV and whose role in pathogenesis requires further elucidation include inflammatory bowel disease, atherosclerosis, cognitive decline, and breast cancer. In **immunocompromised persons** , tissue and bone marrow transplant patients are mainly at risk in the first 100 days after allograft transplantation and in particular when graft-versus-host disease or CMV seropositivity, or both, are present in the donor and recipient. Depending on the serostatus of the donor and recipient, disease may present as primary infection or reactivation. The risk of CMV disease is proportionate to the intensity of immunosuppression. CMV is itself immunosuppressive. CMV may contribute to transplanted organ dysfunction, which often mimics organ rejection. CMV disease in HIV-infected patients (retinitis, serious gastrointestinal disease) occurs most prominently when the CD4 count is < 50 cells/mcL. HAART reduces the frequency of retinitis and may reverse active disease.

CMV retinitis may also develop after solid organ or bone marrow transplantation. CMV retinitis associated with intravitreal delivery of corticosteroids (injections or implants) or systemic anti-tumor necrosis factor-antibodies is also described. Occasionally, CMV retinitis presents in immunocompetent persons. Serious gastrointestinal CMV disease also occurs after organ transplantation, cancer chemotherapy, or corticosteroid therapy. CMV has been identified—often with other pathogens such as *Cryptosporidium*—in up to 15% of patients with AIDS cholangiopathy. CMV pneumonitis occurs in transplant recipients (mainly bone marrow and lung) with a mortality rate up to 60–80%, and less commonly in AIDS patients. CMV pneumonitis in hematologic malignancies (eg, lymphoma) is increasingly reported. Neurologic CMV in patients with advanced AIDS is usually associated with disseminated CMV infection.

Clinical Findings

Symptoms and Signs

Perinatal disease and CMV inclusion disease

CMV inclusion disease in infected newborns is characterized by jaundice, hepatosplenomegaly, thrombocytopenia, purpura, microcephaly, periventricular CNS calcifications, mental retardation, and motor disability. Hearing loss develops in greater than 50% of infants who are symptomatic at birth. Most infected neonates are asymptomatic, but neurologic deficits may ensue later in life. Perinatal infection acquired through breastfeeding or blood products typically shows a benign clinical course.

Disease in immunocompetent persons

Acute acquired CMV infection is characterized by fever, malaise, myalgias and arthralgias, and splenomegaly. Exudative pharyngitis or cervical lymphadenopathies are uncommon, but cutaneous rashes (including the typical maculopapular rash after exposure to ampicillin) are common. The mean duration of symptoms is 7–8 weeks. Notorious complications include mucosal gastrointestinal damage, encephalitis, severe hepatitis, Guillain–Barré syndrome, pericarditis, and myocarditis.

Disease in immunocompromised persons

CMV retinitis

A funduscopic examination reveals neovascular, proliferative lesions ("pizza-pie" retinopathy). Immune restoration with HAART is associated with CMV vitreitis and cystoid macular edema. Infants with CMV retinitis tend to have more macular than peripheral disease.

Gastrointestinal and hepatobiliary CMV

Esophagitis presents with odynophagia. Gastritis can occasionally cause bleeding, and small bowel disease may mimic inflammatory bowel disease or may present as ulceration or perforation. Colonic CMV disease causes diarrhea, hematochezia, abdominal pain, fever, and weight loss. CMV hepatitis commonly complicates liver transplantation.

Respiratory CMV

CMV pneumonitis is characterized by cough, dyspnea, and relatively little sputum production.

Neurologic CMV

Neurologic syndromes associated with CMV include polyradiculopathy, transverse myelitis, ventriculoencephalitis (suspected with ependymitis), and focal encephalitis. These manifestations are more prominent in patients with advanced AIDS in whom the encephalitis has a subacute onset.

Laboratory Findings

PCR assays of dried blood samples from neonates are becoming the easiest method of diagnosing congenital CMV infection and are preferred over serologies or classic throat or urine cultures.

Immunocompetent persons

The acute mononucleosis-like syndrome is characterized by initial leukopenia; within 1 week, it is followed by absolute lymphocytosis with atypical lymphocytes. Abnormal liver function tests are common in the first 2 weeks of the disease (often 2 weeks after the fever). Detection of specific IgM or a fourfold increase of specific IgG levels support the diagnosis of acute infection.

Immunocompromised persons

CMV retinitis is diagnosed on the basis of the characteristic ophthalmoscopic findings. In HIV-infected patients, negative CMV serologies lower the possibility of the diagnosis but do not eliminate it. Cultures alone are of little use in diagnosing AIDS-related CMV infections, since viral shedding of CMV is common. PCR analysis should be used to diagnose CNS infection since cultures are insensitive.

Detection of pp65 antigen in blood and determination of CMV viral load by PCR are increasingly used in posttransplant patients for guidance on both treatment and prevention and should be interpreted in the context of clinical and pathologic findings. PCR appears to be more useful in predicting clinical disease. Quantitative PCR of bronchoalveolar lavage fluid seems to be useful for diagnosing CMV pneumonia.

Rapid shell-vial cultures for detection of early CMV antigens with fluorescent antibodies have largely replaced the conventional tube culture (for detection of cytopathic changes) since the time to positivity is greatly reduced (24–48 hours compared to weeks).

A variety of false-positive immunologic assays occur in the setting of acute CMV infections, including positive rheumatoid factor, direct Coombs test, cryoglobulins, and speckled antinuclear antibody.

Imaging

The chest radiographic findings of CMV pneumonitis are consistent with interstitial pneumonia.

Biopsy

Tissue confirmation is especially useful in diagnosing CMV pneumonitis and CMV gastrointestinal disease; the diagnosis of colonic CMV disease is made by mucosal biopsy showing characteristic CMV histopathologic findings of intranuclear ("owl's eye") and intracytoplasmic inclusions.

Prevention

No vaccine is currently available. HAART is effective in preventing CMV infections in HIV-infected patients. Use of leukocyte-depleted blood products effectively reduces the incidence of CMV disease in patients who have undergone transplantation. Prophylactic and preemptive strategies (eg, antivirals only when antigen detection or PCR assays show evidence of active CMV replication) are effective in preventing disease in the early transplantation period but are associated with a risk of a late-onset form of the disease after the prophylaxis is discontinued. All effective anti-CMV agents can serve as prophylactic agents for CMV-seropositive transplants or for CMV-seronegative recipients of CMV-positive organ transplants. CMV immune globulin may be useful in reducing the incidence of bronchiolitis obliterans in the bone marrow transplant population and is used in some centers as part of the prophylaxis in kidney, liver, and lung transplantation patients.

Withdrawal of infected children from day care centers, reduction of patient contact by health care workers, screening for women of childbearing age, or restrictions to breastfeeding are not recommended because the virus is ubiquitous.

Treatment

Sight-threatening CMV retinitis (lesions close to the fovea or optic nerve head) is treated with ganciclovir induction therapy (5 mg/kg intravenously every 12 hours for 14–21 days) followed by maintenance therapy at lower doses (5 mg/kg intravenously daily). Sustained-release ganciclovir intraocular implants (always accompanied by systemic valganciclovir) are another option. In less severe retinal disease, valganciclovir (900 mg twice daily for 14–21 days followed by 900 mg/d maintenance) is preferred. Due to potential toxicities, foscarnet, cidofovir, and fomivirsen are usually reserved for CMV infections that are resistant to ganciclovir. Combinations of ganciclovir and foscarnet are shown to be safe and effective in treating clinically resistant CMV retinitis. The role of HAART in reducing the need for CMV antivirals is essential. Other forms of CMV disease in AIDS are managed initially with intravenous ganciclovir and subsequently with oral valganciclovir; alternative agents (listed above) are used when resistance evolves.

Therapy for CMV disease resulting from a transplantation procedure is ganciclovir (at same doses as for retinitis) for 2–3 weeks. Oral valganciclovir (900 mg twice daily for 21 days followed by 900 mg daily for 28 days) is noninferior to intravenous ganciclovir-based therapy in solid organ transplant patients with CMV disease and is associated with less clinical resistance than ganciclovir. Dosage adjustments of all medications are needed for kidney dysfunction. Reduction of immunosuppression should be attempted when possible (especially for muromonab, azathioprine, or mycophenolate mofetil). New agents that may be useful in resistant CMV infections include leflunomide, sirolimus-based therapy, and artenusate.

In pregnant women with primary CMV infection, passive immunization with hyperimmune globulin appears preliminarily to be effective in both treatment and prevention of fetal infection, but controlled clinical trials are lacking.

When to Refer

- Neonatal infections consistent with CMV inclusion disease.
- AIDS patients with retinitis, esophagitis, colitis, hepatobiliary disease, or encephalitis.
- Organ transplants with suspected reactivation CMV.

When to Admit

- Risk of colonic perforation.
- Evaluation of unexplained, advancing encephalopathy.
- Biopsy of tissues in the differential diagnosis of transplant rejection vs infection.
- Initiation of treatment with intravenous anti-CMV agents.

Human Herpesviruses 6, 7, & 8

HHV-6 is a B cell lymphotropic virus that is the principal cause of exanthema subitum (roseola infantum, sixth disease). Primary HHV-6 infection occurs most commonly in children under 2 years of age and is a major cause of infantile febrile seizures. HHV-6 is also associated with encephalitis and with acute liver failure. Primary infection in immunocompetent adults is rare and can produce a mononucleosis-like illness. Reactivation of HHV-6 in immunocompetent adults is rare and can present as encephalitis. Infection during pregnancy and congenital transmission is recognized. Most cases of reactivation, however, occur in immunocompromised persons. Reactivation is associated with graft rejection and bone marrow suppression in transplant patients and with encephalitis and pneumonitis in AIDS patients and in recipients of hematopoietic cell transplants. HHV-6 is on occasion also associated with drug-induced hypersensitivity syndromes that may evolve into diabetes mellitus. The roles of HHV-6 in multiple sclerosis, chronic fatigue syndrome, certain malignancies, myocarditis and progressive multifocal leukoencephalopathy remain unproven.

Two variants (A and B) of HHV-6 have been identified. HHV-6B is the predominant strain found in both normal and immunocompromised persons. Ganciclovir and foscarnet (but not acyclovir) appear to be clinically active against HHV-6.

HHV-7 is a T cell lymphotropic virus that is associated with roseola (serologically), seizures and, rarely, encephalitis. Pregnant women are often infected. Infection with HHV-7 is synergistic with CMV in kidney transplant recipients. The membrane glycoprotein CD4 is involved in HHV-7 recognition, but a clinical interaction between HHV-7 and HIV is not established.

HHV-8 is associated with Kaposi sarcoma, multicentric Castleman disease and primary effusion (body cavity) lymphoma. See Chapter 31: HIV Infection & AIDS for pathogenesis and management.

Measles

Essentials of Diagnosis

- Exposure 10–14 days before onset in an unvaccinated patient.
- Prodrome of fever, coryza, cough, conjunctivitis, malaise, irritability, photophobia, Koplik spots.
- Rash: brick-red, irregular, maculopapular; onset 3–4 days after onset of prodrome; begins on the face and proceeds "downward and outward," affecting the palms and soles last.
- Leukopenia.

General Considerations

Measles is a reportable acute systemic paramyxoviral infection transmitted by inhalation of infective droplets. It is a major worldwide cause of pediatric morbidity and mortality, with nearly 800,000 estimated deaths annually. Illness confers permanent immunity. It is highly contagious and communicability is greatest during the preeruptive and catarrhal stages but continues as long as the rash remains. The largest recent outbreak in the Americas was in São Paulo, Brazil, in 1997, with over 42,000 cases among largely unvaccinated young adults. This and other sporadic recent outbreaks of the disease in adults, adolescents, and unvaccinated preschool children in dense urban areas and among sporting events participants emphasize the need for specific recommendations concerning prevention (see below).

In the United States, measles was declared eliminated in 2000. The few reported cases since then are largely imported and geographically dispersed, and the associated isolates fail to show a recurrent strain. Although the number of cases reported during the first half of 2008 was significantly higher than that for previous years, most cases were again associated with importation, especially from Europe. New immigrants and refugees can show serosusceptibility rates to measles in excess of 35%.

Clinical Findings

Symptoms and Signs

(Table 32–2.) Fever is often as high as 40–40.6 °C. It persists through the prodrome and early rash (about 5–7 days). Malaise may be marked. Coryza (nasal obstruction, sneezing, and sore throat) resembles that seen with upper respiratory infections. Cough is persistent and nonproductive. Conjunctivitis manifests as redness, swelling, photophobia, and discharge. These symptoms intensify over the 2–4 days before the onset of the rash and peak on the first day of the rash.

Koplik spots (small, irregular, and red with whitish center on the mucous membranes) are pathognomonic of measles. They appear about 2 days before the rash and last 1–4 days as tiny "table salt crystals" in the buccal mucosa opposite the molars and vaginal membranes. The rash usually appears on the face and behind the ears 4 days after the onset of symptoms. The initial lesions are pinhead-sized papules that coalesce to form a brick-red, irregular, blotchy maculopapular rash. In severe cases, the rash coalesces to form a nearly uniform erythema on some body areas. The rash next appears on the trunk, followed by the extremities, including the palms (25–50% of those infected) and soles. The rash lasts for 3–7 days and fades in the same manner it appeared. Hyperpigmentation remains in fair-skinned individuals and severe cases. Slight desquamation may follow.

Other findings in measles include pharyngeal erythema, a tonsillar yellowish exudate, coating of the tongue in the center with a red tip and margins, moderate generalized lymphadenopathy and, at times, splenomegaly.

Atypical measles is a syndrome occurring in adults who received inactivated measles vaccine (1963–1968) or who received live measles vaccine before age 12 months and as a result developed hypersensitivity rather than protective immunity. When persons are infected later with wild measles virus, a potentially fatal illness may develop, with high fever; unusual rashes (papular, hemorrhagic), most prominent on the extremities, without Koplik spots; headache; arthralgias; hepatitis; a high rate of pneumonitis, and sometimes pleural effusions. Measles antibody titers tend to be very high after the appearance of the exanthem.

Measles may be distinctive in HIV-infected individuals, with higher rates of pneumonitis, higher mortality, and prolonged viral shedding. Vaccine failure rates, primary and secondary, are higher in HIV-infected children. The frequent difficulty in establishing a diagnosis suggests that measles may be more prevalent in epidemics than heretofore recognized.

Measles during pregnancy is not known to cause congenital abnormalities of the fetus. It is, however, associated with spontaneous abortion and premature delivery and can cause severe disease in the mother. Although measles does not always develop in the offspring of mothers with the disease, it can be severe when it does. It is therefore recommended that infants born to such mothers be passively immunized with immunoglobulin at birth.

The virologic clearance of measles can take months.

Laboratory Findings

Leukopenia is usually present unless secondary bacterial complications exist. A lymphocyte count under 2000/mcL is a poor prognostic sign. Thrombocytopenia is common. Proteinuria is often observed. Although technically difficult, virus can be cultured from nasopharyngeal washings and from blood. Detection of IgM measles antibodies with enzyme-linked immunosorbent assay (ELISA) or a fourfold rise in serum hemagglutination inhibition antibody supports the diagnosis. Fluorescent antibody staining of respiratory or urinary epithelial cells can also confirm the diagnosis. PCR techniques are available in research settings.

Differential Diagnosis

Measles is usually diagnosed clinically but may be mistaken for other exanthematous infections (see Table 32–2).

Complications

Central Nervous System

Postinfectious encephalomyelitis occurs in about 0.05–0.1% of cases. Higher rates of encephalitis occur in adolescents and adults than in school-aged children. Its onset is usually 3–7 days after the rash. Vomiting, convulsions, coma, and diverse, severe neurologic symptoms and signs may develop. Treatment is symptomatic and supportive. Virus is usually not found in the CNS, though demyelination is prominent. There is an appreciable mortality rate (10–20%), and 33% of survivors are left with neurologic deficit.

A similar form, "inclusion body encephalitis," occurs months after exposure. This complication is reported to occur after measles vaccination in patients with inadequate cellular immunity but is associated with isolation of the measles virus.

Subacute sclerosing panencephalitis (SSPE) is a very late CNS complication (5–15 years after infection); the measles virus acts as a "slow virus" to produce degenerative CNS disease years after the initial infection. SSPE is rare (1:100,000 cases of measles) and occurs more often when measles develops early in life among males who live in rural environments. SSPE very rarely develops in adults.

Measles virus can opportunistically invade the CNS. An acute progressive encephalitis (subacute measles encephalitis), characterized by seizures, neurologic deficits, and often progressive stupor and death, can occur among immunosuppressed patients. Treatment is supportive, withholding immunosuppressive chemotherapy when feasible. Interferon and ribavirin are variably successful.

Respiratory Tract Disease

Early in the course of the disease, bronchopneumonia or bronchiolitis due to the measles virus may occur in up to

5% of patients and result in serious respiratory difficulties. Bronchiectases may occur in up to a quarter of nonvaccinated children. Pneumonia occurring with or without an evanescent rash is seen in atypical measles.

Secondary Bacterial Infections

Immediately following measles, secondary bacterial infection, particularly cervical adenitis, otitis media (the most common complication), and pneumonia, occurs in about 15% of patients.

Immune Reactivity

Measles produces temporary anergy to cell-mediated skin tests.

Gastroenteritis

Diarrhea and protein-losing enteropathy (prodromal rectal Koplik spots may be seen) are significant complications among malnourished children.

Other Complications

Other complications include conjunctivitis, keratitis, and otosclerosis.

Prevention

In the United States, children receive their first vaccine dose at 12–15 months and a second at age 4–6 years prior to entry into school (see Table 32–2). Combination measles-mumps-rubella-varicella vaccines (MMRV) can be used in place of the traditional measles, mumps, and rubella (MMR) vaccine.

American students beyond high school and medical staff starting employment require documentation of the above vaccination schedule or must show serologic evidence of immunity if they were born after 1956. For individuals born before 1957, herd immunity is assumed. Health care workers, immigrants, and refugees should be screened and vaccinated if necessary regardless of date of birth.

In outbreaks occurring in infants under 1 year of age, initial vaccination may be given at 6 months, with repeat at 15 months. When outbreaks take place in day care centers, K–12 institutions, or colleges and universities, revaccination is probably indicated for all, in particular for students and their siblings born after 1956 who do not have documentation of immunity as defined above. Susceptible personnel who have been exposed should be isolated from patient contact between the fifth and the twenty-first day after exposure regardless of whether they were vaccinated or given immune globulin. If measles develop in these persons, they should be isolated from patient contact until 7 days after the rash develops.

When susceptible individuals are exposed to measles, the live virus vaccine can prevent disease if given within 5 days of exposure. In addition, immune globulin (0.25 mL/kg [0.11 mL/lb] body weight) can be injected intramuscularly for prevention or modification of clinical illness if given within 6 days after exposure. This must be followed by active immunization with live measles vaccine 3 months later. Vaccination of all immunocompetent persons born after 1956 who travel to the developing world is important. In the developing world, the use of the second vaccine dose is an important aspect of achieving control of measles in the community-at-large.

Pregnant women and immunosuppressed persons should *not* receive this vaccine. The exception to this contraindication is asymptomatic HIV-infected patients including children, who have not shown adverse effects from measles vaccination. In asymptomatic HIV-infected children, exposure to vaccines improves survival after measles, and HAART therapy is associated with an improved vaccine response. Repeat vaccination may be necessary in HIV-infected children. Immune globulin should be considered for postexposure prophylaxis in any high-risk person exposed to measles. This group includes children with malignant disease and patients with AIDS, in whom severe disease or fatal measles is likely to develop. To be effective, immune globulin should be administered within 6 days after an exposure.

Severe allergic reactions to the MMR vaccine are rare, though fever and rash appear to occur slightly more often among female recipients. An aerosolized measles vaccine shows promising results in small clinical trials with hopes for availability in the near future. Future vaccines for a variety of infectious agents may utilize measles vectors, thereby augmenting immunity to measles.

Treatment

General Measures

The patient should be isolated for the week following onset of rash and kept at bed rest until afebrile. Treatment is symptomatic including antipyretics and fluids as needed. Vitamin A, 200,000 units/d orally for 2 days (the benefit being maintenance of gastrointestinal and respiratory epithelial mucosa), reduces pediatric morbidity rates although high-dose vitamin A exposure increases the severity and risk of antibiotic failure in nonmeasles pneumonia. Measles virus is susceptible to ribavirin in vitro and has been used in selected severe cases of pneumonitis (35 mg/kg/d intravenously in three divided doses for 2 days, followed by 20 mg/kg/d intravenously in three divided doses for 5 days).

Treatment of Complications

Secondary bacterial infections, including pneumonia, are treated with appropriate antibacterial antibiotics.

Postmeasles encephalitis, including SSPE, can be managed only symptomatically.

Prognosis

Between 1999 and 2005, measles mortality rate was reduced an estimated 60%. In the last decade, the case-fatality rate in the United States stayed around 3 per 1000 reported cases, with deaths principally due to encephalitis (15% mortality rate) and secondary bacterial pneumonia. Deaths in the developing world are mainly related to diarrhea and protein-losing enteropathy.

When to Refer

- Any suspect cases should be reported to public health authorities.
- HIV infection.
- Pregnancy.

When to Admit

- Meningitis, encephalitis, or myelitis.
- Severe pneumonia.
- Diarrhea that significantly compromises fluid or electrolyte status.

Mumps

Essentials of Diagnosis

- Exposure 14–21 days before onset.
- Painful, swollen salivary glands, usually parotid.
- Frequent involvement of testes, pancreas, and meninges in unvaccinated individuals.

General Considerations

Mumps is a paramyxoviral disease spread by respiratory droplets. While children are the age group most affected, recent outbreaks involved patients in the late second or early third decades of life. The incidence of mumps is highest in spring. The incubation period is 14–21 days (average, 18 days). Infectivity occurs via saliva and urine and precedes the symptoms by about 1 day and is maximal for 3 days, although it may last a week. Up to one-third of affected individuals have subclinical infection. In 2006, an outbreak of mumps in the United States occurred and involved over 6000 persons; 85% of these cases were reported from eight Midwestern states.

Clinical Findings

Symptoms and Signs

Mumps is more serious in adults than in children. Parotid tenderness and overlying facial edema are the most common physical findings (Plate 98) and typically develop within 48 hours of the prodromal symptoms. Usually, one parotid gland enlarges before the other, but unilateral parotitis alone occurs in 25% of patients. The orifice of Stensen duct may be red and swollen. Trismus may result from parotitis. The parotid glands return to normal within a week. Involvement of other salivary glands (submaxillary and sublingual) occurs in 10% of cases.

Plate 98.

Mumps. (Public Health Image Library, CDC.)

Fever and malaise are variable but often minimal in young children. High fever accompanies meningitis or orchitis. Neck stiffness, headache, and lethargy suggest meningitis. Testicular swelling and tenderness (unilateral in 75% of cases) denote orchitis; the testes are the most common extrasalivary site of disease in adults. Orchitis develops 7–10 days after the onset of parotitis in about 25–40% of postpubertal men, but sterility is rare. Upper abdominal pain, nausea, and vomiting suggest pancreatitis. Mumps is the leading cause of pancreatitis in children. Lower abdominal pain and ovarian enlargement suggest oophoritis (which occurs in 5% of postpubertal women, usually unilateral); it is a difficult diagnosis to establish.

Laboratory Findings

Mild leukopenia with relative lymphocytosis may be present. Serum amylasemia usually reflects salivary gland involvement rather than pancreatitis. Lymphocytic pleocytosis (and hypoglychorrhachia) of the cerebrospinal fluid in meningitis may be asymptomatic. Mild kidney function abnormalities are found in up to 60% of patients.

A characteristic clinical picture is usually sufficient for diagnosis. A confirmatory diagnosis of mumps is made by isolating the virus preferably from a swab of the duct of the parotid or other affected salivary gland. The virus can also be isolated from cerebrospinal fluid early in the course of aseptic meningitis. Isolation from urine is no longer advised. Nucleic acid amplification techniques are more sensitive than viral cultures but their availability is limited. An elevated serum IgM is also considered diagnostic and a repeat test 2–3 weeks after the onset of symptoms is recommended if the first assay is negative due to a delay in IgM rise, especially in vaccinated persons. A fourfold rise in complement-fixing antibodies to mumps virus in paired serum IgG also confirms infection.

Differential Diagnosis

Swelling of the parotid gland may be due to calculi in the parotid ducts, tumors, or cysts, or to a reaction to iodides. Other causes include starch ingestion, sarcoidosis, cirrhosis, diabetes, bulimia, pilocarpine usage, and Sjögren syndrome. Parotitis may be produced by pyogenic organisms (eg, *S aureus*, gram-negative organisms), particularly in debilitated individuals with poor oral intake, drug reaction (phenothiazines, propylthiouracil), and other viruses (influenza A, parainfluenza, EBV infection, coxsackieviruses, adenoviruses, HHV-6). Swelling of the parotid gland must be differentiated from inflammation of the lymph nodes located more posteriorly and inferiorly than the parotid gland.

Complications

Other manifestations of the disease are less common. These usually follow the parotitis but may precede it or occur without salivary gland involvement and include meningitis (30%), orchitis (which on rare occasion leads to priapism or testicular infarction), pancreatitis (usually mild), oophoritis, thyroiditis, neuritis, hepatitis, myocarditis, thrombocytopenia, migratory arthralgias (noted infrequently among adults and rarely in children), and nephritis. Mumps has also been associated with cases of endocardial fibroelastosis.

Rare neurologic complications include encephalitis, Guillain–Barré syndrome, cerebellar ataxia, facial palsy, and transverse myelitis. Encephalitis is associated with cerebral edema, serious neurologic manifestations, and sometimes death. Deafness develops from eighth nerve neuritis, and data from Japan report an incidence of 0.3% among patients.

Prevention

Mumps live virus vaccine is safe and highly effective with long lasting immunity. It is recommended for routine immunization for children over age 1 year, either alone or in combination with other virus vaccines (eg, in the measles-mumps-rubella (MMR) vaccine or as a quadrivalent vaccine with varicella). A second dose is recommended for children (ages 4–6 years) before starting school. Two doses of the vaccine should also be considered for high-risk individuals (eg, health care workers) born before 1957 and without evidence of immunity. There are no known cases of long-term sequelae associated with mumps vaccination and the currently used mumps strain (Jeryl Lynn) shows the lowest associated incidence of postvaccine aseptic meningitis (from 1 in 150,000 to 1 in 1.8 million). This vaccine is less effective in epidemic than in nonepidemic settings. Reactions are reviewed in the measles section. It should not be given to pregnant women or to immunocompromised individuals, though the vaccine has been given to asymptomatic HIV-infected individuals without adverse sequelae especially when the individuals are taking HAART. In the developed world, persons in whom mumps develops are less likely to have received a second vaccine dose. The mumps skin tests are less reliable than serum neutralization titers in determining immunity.

Treatment

General Measures

The patient should be isolated until swelling subsides (about 9 days from onset) and kept at bed rest while febrile. Treatment is symptomatic. Topical application of compresses may relieve parotid discomfort.

Management of Complications

Meningitis

The treatment of aseptic meningitis is symptomatic. The management of encephalitis requires attention to cerebral edema, the airway, and vital functions.

Orchitis

The scrotum should be supported with a suspensory or toweling "bridge" and ice bags applied. Incision of the tunica may be necessary in severe cases. Pain can be relieved with opioids, or by injecting the spermatic cord at the external inguinal ring with 10–20 mL of 1% procaine solution. The merit of hydrocortisone sodium succinate (100 mg intravenously, followed by 20 mg orally every 6 hours for 2 or 3 days) in reducing inflammation is not firmly established.

Pancreatitis

Symptomatic treatment should be provided with emphasis on parenteral hydration.

Prognosis

The entire course of mumps rarely exceeds 2 weeks. Rare fatalities are usually due to encephalitis.

When to Refer

Any suspect cases should be reported to public health authorities.

When to Admit

- Trismus.
- Meningitis, encephalitis.
- Severe abdominal pain or vomiting suggesting pancreatitis.
- Severe testicular pain.
- Priapism.
- Severe thrombocytopenia.
- Myocarditis.

Poliomyelitis

Essentials of Diagnosis

- Incubation period 9–12 days from exposure.
- Muscle weakness, headache, stiff neck, fever, nausea and vomiting, sore throat.
- Lower motor neuron lesion (flaccid paralysis) with decreased deep tendon reflexes and muscle wasting.
- Cerebrospinal fluid shows excess leukocytes, with lymphocytic predominance; count is rarely more than 500/mcL.

General Considerations

Poliomyelitis virus, an enterovirus, is present in throat washings and stools (excretion may last for several weeks after infection). Infection is highly contagious through the fecal–oral route, especially during the first week of the disease. The global poliomyelitis eradication initiative was launched in 1988 and led to the virtual elimination of wild poliovirus from the Western hemisphere (a few cases of vaccine-associated disease were reported in Hispaniola, see below). The Pacific Rim and much of Central Asia also appear to be polio free. Between 1988 and 2007, the number of cases decreased globally from 350,000 to just over 1000 (see illustration). Only four countries had not yet documented interruption of wild poliovirus transmission (Afghanistan, India, Nigeria, and Pakistan).

Resurgence in wildtype polio cases and vaccine-derived poliomyelitis still pose problems for elimination of poliomyelitis virus. Recent vaccine-associated cases were reported from Cambodia, Myanmar, and Nigeria, and cases among immunodeficient persons were reported from China, Iran, Syria, and Egypt. The last vaccine-associated case in the United States occurred in 2005; the woman acquired the infection while traveling in Central America.

Fig.
Total number of reported paralytic poliomyelitis cases (excluding imported cases) and number of reported vaccine-associated cases–United States, 1960–1994. (Reproduced from Paralytic poliomyelitis–United States, 1980–1994. MMWR Morb Mortal Wkly Rep 1997;46:79.)

Three antigenically distinct types of poliomyelitis virus are recognized, with little cross-immunity between them. Disease with type 2 in particular is on the verge of extinction.

Clinical Findings

Symptoms and Signs

At least 95% of infections are asymptomatic, but in those who become ill manifestations include abortive poliomyelitis (minor illness), nonparalytic poliomyelitis, and paralytic poliomyelitis.

Abortive poliomyelitis (minor illness)

Such minor illness occurs in 4–8% of infections and the symptoms are fever, headache, vomiting, diarrhea, constipation, and sore throat lasting 2–3 days. This entity is suspected clinically only during an epidemic.

Nonparalytic poliomyelitis

In addition to the above symptoms, signs of meningeal irritation and muscle spasm occur in the absence of frank paralysis. This disease is indistinguishable from aseptic meningitis caused by other viruses.

Paralytic poliomyelitis

Paralytic poliomyelitis represents 0.1% of all poliomyelitis cases (the incidence is higher when infections are acquired later in life). Paralysis may occur at any time during the febrile period. Tremors, muscle weakness, constipation, and ileus may appear. Paralytic poliomyelitis is divided into two forms, which may coexist: (1) **spinal poliomyelitis**, with involvement of the muscles innervated by the spinal nerves, and (2) **bulbar poliomyelitis**, with weakness of the muscles supplied by the cranial nerves (especially nerves IX and X) and of the respiratory and vasomotor centers.

In spinal poliomyelitis, paralysis of the shoulder girdle often precedes intercostal and diaphragmatic paralysis, which leads to diminished chest expansion and decreased vital capacity. The paralysis occurs over 2–3 days, is flaccid, has an asymmetric distribution, and affects the proximal muscles of the lower extremities more frequently. Sensory loss is very rare.

In bulbar poliomyelitis, symptoms include diplopia (uncommonly), facial weakness, dysphagia, dysphonia, nasal voice, weakness of the sternocleidomastoid and trapezius muscles, difficulty in chewing, inability to swallow or expel saliva, and regurgitation of fluids through the nose. The most life-threatening aspect of bulbar poliomyelitis is respiratory paralysis. Lethargy or coma may be due to hypoxia, most often from hypoventilation. Vasomotor disturbances in blood pressure and heart rate may occur. Convulsions are rare. Bulbar poliomyelitis is more common in adults.

Laboratory Findings

The peripheral white blood cell count may be normal or mildly elevated. Cerebrospinal fluid pressure and protein are normal or slightly increased. Glucose is not decreased. White blood cells usually number < 500/mcL and are principally lymphocytes after the first 24 hours. Cerebrospinal fluid is normal in 5% of patients. The virus may be recovered from throat washings (early) and stools (early and late). Neutralizing and complement-fixing antibodies appear during the first or second week of illness. Serologic testing cannot distinguish between wild-type and vaccine-related virus infections.

Differential Diagnosis

Nonparalytic poliomyelitis is similar to other forms of enteroviral meningitis; the distinction is made serologically. Acute flaccid paralysis is the term used in the developing world for the variety of neurologic illnesses that both include and mimic poliomyelitis. Acute flaccid paralysis due to poliomyelitis is distinguished by the greater frequency of fever and asymmetric neurologic signs. Acute inflammatory polyneuritis (Guillain–Barré syndrome), Japanese B virus encephalitis, West Nile virus infection, and tick paralysis may resemble poliomyelitis. In Guillain–Barré syndrome (see Chapter 24: Nervous System Disorders), the weakness is more symmetric and ascending in most cases, but the Miller–Fisher variant is quite similar to bulbar polio. Paresthesias are uncommon in poliomyelitis but common in Guillain–Barré syndrome. The cerebrospinal fluid usually has a high protein content but normal cell count in Guillain–Barré syndrome.

Complications

Urinary tract infection, atelectasis, pneumonia, myocarditis, paralytic ileus, gastric dilation, and pulmonary edema may occur. Respiratory failure may be a result of paralysis of respiratory muscles, airway obstruction from involvement of cranial nerve nuclei, or lesions of the respiratory center.

Prevention

Given the epidemiologic distribution of poliomyelitis and the continued concern about vaccine-associated disease (estimated in 1:750,000 recipients) with the trivalent oral live poliovirus vaccine (OPV), the inactive (Salk) parenteral vaccination is currently used in the United States for all four recommended doses (at ages 2 months, 4 months, and 6–18 months and at 4–6 years). Inactivated vaccine is also routinely used elsewhere in the developed world. Oral vaccines are limited to usage for outbreak control, travel to endemic areas within the ensuing month, and protection of children whose parents do not comply with the recommended number of immunizations. The advantages of oral vaccination are the ease of administration, low cost, effective local gastrointestinal and circulating immunity, and herd immunity.

Routine immunization of adults in the United States is no longer recommended because of the low incidence of the disease. Exceptions include adults not vaccinated within the prior decade who are exposed to poliomyelitis or who plan to travel to endemic areas (mentioned above). Vaccination should also be considered for adults engaged in high-risk activities (eg, laboratory workers handling stools). Such adults should be given inactivated poliomyelitis vaccine (Salk) as should immunodeficient or immunosuppressed individuals and members of their households.

In the developing world, three doses of OPV seem sufficient for adequate immunization and the interval between doses should probably be longer than 1 month (because of interference from enteric pathogens). Intramuscular injections should be routinely avoided during the month following oral poliomyelitis vaccination to prevent provocation paralysis. Ancillary useful control measures in polio-endemic countries include national immunization days (mass campaigns in which all children are vaccinated twice, 4–6 weeks apart, regardless of vaccine history); cross-border vaccination activities; surveillance for acute flaccid paralysis, an indicator for poliomyelitis; and aggressive outbreak responses as well as intensified immunization activities in countries recently affected by armed conflicts. Vaccine-associated poliomyelitis with the oral Sabin vaccination is due to mutations leading to neurovirulence. Outbreaks of vaccine-derived poliomyelitis are reported sporadically globally (listed above) with the last major outbreak in the Western Hemisphere occurring in Hispaniola (both Haiti and the Dominican Republic) from 2000 to 2001. Such incidents serve as a reminder of the need to maintain high levels of immunization coverage even in the absence of overt disease. A monovalent type 1 oral vaccine that seems more immunogenic than the three-valent OPV and has the advantage of single administration was successfully used in India, Egypt, and Nigeria. Cost considerations along with effective herd immunity remain major reasons the oral Sabin is still administered.

There is no epidemiologic evidence to implicate poliomyelitis vaccination as a cause for recurrent worsening wheezing or eczema in childhood.

Treatment

In the acute phase of paralytic poliomyelitis patients should be hospitalized. Strict bed rest in the first few days of illness reduces the rate of paralysis. Cranial nerve involvement must be vigilantly sought. Comfortable but rotating positions should be maintained in a "polio bed": firm mattress, footboard, sponge rubber pads or rolls, sandbags, and light splints. Intensive physiotherapy may help recover some motor function with paralysis. Fecal impaction and urinary retention (especially with paraplegia) are managed appropriately. In cases of respiratory weakness or paralysis, intensive care is needed. The antiviral pleconaril shows no clear benefit in cases of polio meningoencephalitis.

Prognosis

During the febrile period, paralysis may develop or progress. Mild weakness of small muscles is more likely to regress than is severe weakness of large muscles. Bulbar poliomyelitis carries a mortality rate of up to 50%. New muscle weakness and pain may develop and progress slowly years after recovery from acute paralytic poliomyelitis. This entity is called **postpoliomyelitis syndrome** and presents with signs of chronic and new denervation, is not infectious in origin, and patients do not shed the virus. The syndrome is associated with increasing dysfunction of surviving motor neurons. Different immune modulators such as prednisone, interferon, and intravenous immunoglobulin have been tested for treatment of postpoliomyelitis syndrome but have not shown clear benefits. Series that report increased incidences of multiple sclerosis or other motor neuron diseases among poliomyelitis survivors need to be evaluated in the context of what is known about the postpoliomyelitis syndrome. Although bulbar poliomyelitis causes the greatest threat to life, it is rarely responsible for permanent damage among surviving patients.

When to Refer

- Neurologic compromise.
- Any suspicious cases should be referred to public

health authorities.

When to Admit

Patients with neurologic compromise should be admitted to the hospital.

Rubella

Essentials of Diagnosis

- Exposure 14–21 days before onset.
- Arthralgia, particularly in young women.
- No prodrome in children, mild prodrome in adults; mild symptoms (fever, malaise, coryza) coinciding with eruption.

- Posterior cervical and postauricular lymphadenopathy 5–10 days before rash.
- Fine maculopapular rash of 3 days duration; face to trunk to extremities.
- Leukopenia, thrombocytopenia.

General Considerations

Rubella is a systemic disease caused by a togavirus transmitted by inhalation of infective droplets. It is only moderately communicable. One attack usually confers permanent immunity but reinfection is possible. The incubation period is 14–21 days (average, 16 days). The disease is transmissible from 1 week before the rash appears until 15 days afterward.

The clinical picture of rubella is difficult to distinguish from other viral illnesses such as infectious mononucleosis, measles, echovirus infections, and coxsackievirus infections; however, arthritis is more prominent in rubella. In the United States, endemic rubella and congenital rubella syndrome are eliminated. Surveillance of female military recruits suggests, however, that serologic protection against rubella, measles, and mumps are inadequate. In 2004, fewer than ten cases were reported to the Centers for Disease Control and Prevention (CDC) with all them likely imported from other countries. In parts of the world (eg, Eastern Europe) where vaccination against rubella was more recently introduced, significant outbreaks still occur. Serosusceptibility to the infection in immigrants to developed countries is still significant.

The principal importance of rubella lies in its devastating effects on the fetus in utero, producing teratogenic effects and a continuing congenital infection. More than 100,000 cases of **congenital rubella syndrome** are reported annually in the developing world.

Clinical Findings

Symptoms and Signs

While fetal rubella can be devastating, postnatally acquired rubella is usually innocuous with up to 50% cases asymptomatic. In the postnatally acquired infection, fever and malaise, usually mild, accompanied by tender suboccipital adenitis, may precede the eruption by 1 week. Mild coryza may be present. Polyarticular arthritis occurs in about 25% of adult cases and involves the fingers, wrists, and knees. Rarely does chronic arthritis develop. The polyarthritis usually subsides within 7 days but may persist for weeks. Early posterior cervical and postauricular lymphadenopathy is very common. Erythema of the palate and throat, sometimes patchy, may be noted.

A fine, pink maculopapular rash appears on the face, trunk, and extremities in rapid progression (2–3 days) and fades quickly, usually lasting 1 day in each area (Table 32–2). Rubella without rash may be at least as common as the exanthematous disease. Diagnosis, when suspected because of disease in the community, requires serologic confirmation.

Laboratory Findings

Leukopenia may be present early and may be followed by an increase in plasma cells. The definitive diagnosis of acute rubella infection is based on elevated IgM antibody, fourfold or greater rise in IgG antibody titers, or isolation of the virus. False-positive IgM antibodies, however, are associated with Epstein-Barr virus, cytomegalovirus, parvovirus, and rheumatoid factor. Detection of antibodies against rubella in other body fluids, such as urine and saliva, seem promising diagnostic aids. PCR techniques are also available.

Complications

Exposure During Pregnancy

When a pregnant woman is exposed to a possible case of rubella, an immediate hemagglutination-inhibiting rubella antibody level should be obtained to document immunity, since fetal infection during the first trimester leads to congenital rubella in at least 80% of fetuses.

Positive tests for IgG antibodies alone indicate past infection or vaccination. If no antibodies are found, clinical observation and serologic follow-up are essential. An isolated IgM-positive test needs to be interpreted with caution because it does not necessarily imply acute infection. Confirmation of rubella in the expectant mother raises the question of therapeutic abortion, an alternative to be considered in light of personal, religious, legal, and other factors.

Congenital Rubella

An infant acquiring the infection in utero may be normal at birth but probably—50% in a series of nearly 70 pregnant women with rubella in Mexico—will have a wide variety of manifestations, including early-onset cataracts and glaucoma, microphthalmia, hearing deficits, psychomotor retardation, congenital heart defects, organomegaly, and maculopapular rash. In general, the younger the fetus when infected, the more severe the illness. Deafness is the primary complication in the second trimester. Viral excretion in the throat and urine persists for many months despite high antibody levels. A specific test for IgM rubella antibody is useful for diagnosis in the newborn. A confirmatory diagnosis is made by isolation of the virus or PCR detection of viral RNA in tissues. Treatment is directed toward the many anomalies.

Postinfectious Encephalopathy

In 1:6000 cases, postinfectious encephalopathy develops 1–6 days after the rash; the virus cannot always be isolated. The mortality rate is 20%, but residual deficits are rare among the recovered. The mechanism is unknown.

Other unusual complications of rubella include hemorrhagic manifestations due to thrombocytopenia and vascular damage, duodenal stenosis, and mild hepatitis.

Prevention

Live attenuated rubella virus vaccine should be given to all infants and to susceptible girls before the menarche. When women are immunized, they should not be pregnant, and the absence of antibodies should be established. (In the United States, about 80% of 20-year-old women are immune to rubella.) Postpartum administration to susceptible female hospital employees is recommended. It is recommended that women not become pregnant for at least 3 months after vaccine administration. Nonetheless, there are no reports of congenital rubella syndrome after rubella immunization, and inadvertent immunization of a pregnant woman is not considered an indication for therapeutic abortion. Arthritis is more marked after rubella vaccination than in native disease and appears to be immunologically mediated. The association between chronic arthropathies and rubella vaccination is controversial. MMR may be given in conjunction with diphtheria–pertussis–tetanus (DPT) boosters as adequate serologic responses are documented. The administration of two or more doses appears to overcome an immunogenetic risk for vaccine failure in some vaccinees.

Treatment

Acetaminophen provides symptomatic relief. Encephalitis and non-life-threatening thrombocytopenia should be treated symptomatically.

Prognosis

Rubella is a mild illness and rarely lasts more than 3–4 days. Congenital rubella, on the other hand, has a high mortality rate, and the associated congenital defects are largely permanent.

When to Refer

- Pregnancy.
- Meningitis/encephalitis.
- Any suspect cases should be reported to public health authorities.

Rabies

Essentials of Diagnosis

- History of animal bite.
- Paresthesia, hydrophobia, rage alternating with calm.
- Convulsions, paralysis, thick tenacious saliva.

General Considerations

Rabies is a viral (rhabdovirus) encephalitis transmitted by infected saliva that gains entry into the body by an animal bite or an open wound. Globally, an estimated 50,000 to 100,000 deaths occur annually from rabies, mostly in rural areas of Africa and Asia. In the United States, domestically acquired rabies cases are rare but probably underreported. One bat-associated human case was reported from Minnesota in 2007. Raccoons, skunks, bats, and foxes are common wildlife reservoirs. Unique geographic biting species that cause rabies in the United States include raccoons in the East, including New England; skunks in the Midwest, Southwest, and in California; and foxes in the Southwest and in Alaska. Bats are the second most reported rabid animal behind raccoons and most cases in the United States from 2000 through 2006 (17 of 24 total) were associated with bat rabies virus variants. Hawaii is the only rabies-free state. Vaccination campaigns are very successful in preventing dog-associated cases. Cats are rarely infected in the United States, although an increase in the number of cases was reported in 2006. Rodents and lagomorphs (eg, rabbits) are unlikely to spread rabies because they cannot survive the disease long enough to transmit it, although woodchucks and groundhogs can become infected and transmit the virus. In developing countries, greater than 90% of human cases are due to infected dog bites. Rabies among travelers to rabies-endemic areas (usually the Middle East and sub-Saharan Africa) is usually associated with animal injuries.

The virus gains entry into the salivary glands of dogs 5–7 days before their death from rabies, thus limiting their period of infectivity. Less common routes of transmission include contamination of mucous membranes with saliva or brain tissue, aerosol transmission, and corneal transplantation. Transmission through solid organ and vascular segment transplantation from donors with unrecognized infection is also reported.

The incubation period may range from 10 days to many years but is usually 3–7 weeks depending in part on the distance of the wound from the CNS. The virus travels in the nerves to the brain, multiplies there, and then migrates along the efferent nerves to the salivary glands (see micrograph); (see micrograph); (see micrograph); (see micrograph).

Rabies is almost uniformly fatal, with only six documented surviving cases to date. Five received either preexposure or postexposure prophylaxis. In 2004, a teenager survived with only naturally acquired immunity, but received intense treatment including antiviral therapy and an intentionally induced drug coma. The most common clinical problem confronting clinicians is the management of a patient bitten by an animal.

Clinical Findings

Symptoms and Signs

While there is usually a history of animal bite, bat bites may not be recognized. The prodromal syndrome consists of pain at the site of the bite in association with fever, malaise, headache, nausea, and vomiting. The skin is sensitive to changes of temperature, especially air currents (aerophobia). Percussion myoedema can be present and persist throughout the disease. The CNS stage begins about 10 days after the prodome and may be either encephalitic ("furious") or paralytic ("dumb"). The encephalitic form (about 80% of the cases) produces the classic rabies manifestations of delirium alternating with periods of calm, extremely painful laryngeal spasms on attempting drinking (hydrophobia), autonomic stimulation (hypersalivation), and seizures. In the less common paralytic form, an acute ascending paralysis resembling Guillain–Barré syndrome predominates with relative sparing of higher cortical functions initially. Both forms progress relentlessly to coma, autonomic nervous system dysfunction, and death.

Laboratory Findings

Biting animals that appear well should be quarantined and observed for 10 days. Sick or dead animals should be tested for rabies. A wild animal, if captured, should be sacrificed and the head shipped on ice to the nearest laboratory qualified to examine the brain for evidence of rabies virus. When the animal cannot be examined, raccoons, skunks, bats, and foxes should be presumed to be rabid.

Direct fluorescent antibody testing of skin biopsy material from the posterior neck (where hair follicles are highly innervated) has a sensitivity of 60–80%.

Reverse transcriptase PCR (RT-PCR), nucleic acid sequence-based amplification, and viral isolation from the cerebrospinal fluid or saliva are being advocated as definitive diagnostic assays. Antibodies can be detected in the serum and the cerebrospinal fluid. Pathologic specimens often demonstrate round or oval eosinophilic inclusion bodies (Negri bodies) in the cytoplasm of neuronal cells, but the finding is neither sensitive nor specific. MRI signs are diffuse and nonspecific.

Prevention

Immunization of household dogs and cats and active immunization of persons with significant animal exposure (eg, veterinarians) are important. The most important decisions, however, concern animal bites.

In the developing world, education, surveillance, and animal (particularly dog) vaccination programs are preferred over mass destruction of dogs, which is followed typically by invasion of susceptible feral animals into urban areas. In some Western European countries, campaigns of oral vaccination of wild animals led to the elimination of rabies in wildlife.

Local Treatment of Animal Bites and Scratches

Thorough cleansing, debridement, and repeated flushing of wounds with soap and water are important. Rabies immune globulin or antiserum should be given as stated below. Wounds caused by animal bites should not be sutured.

Postexposure Immunization

The decision to treat should be based on the circumstances of the bite, including the extent and location of the wound, the biting animal, the history of prior vaccination, and the local epidemiology of rabies. Any contact or suspect contact with a bat is usually deemed a sufficient indication to warrant prophylaxis. Consultation with state and local health departments is recommended. Postexposure treatment including both immune globulin and vaccination should be administered as promptly as possible when indicated.

The optimal form of passive immunization is human rabies immune globulin (HRIG; 20 international units/kg), administered once. As much as possible of the full dose should be infiltrated around the wound, with any remaining injected intramuscularly at a site distant from the wound. Finger spaces can be safely injected without development of a compartment syndrome. If HRIG is not available, equine rabies antiserum (20–40 international units/kg) can be used if available (it was last produced in 2001) after appropriate tests for horse serum sensitivity.

Two vaccines are licensed and available for use in humans in the United States: a human diploid cell vaccine (HDCV) and a purified chick embryo cell vaccine (PCEC). The current vaccines are given as five injections of 1 mL intramuscularly in the deltoid or, in small children, into the anterolateral thigh muscles on days 0, 3, 7, 14, and 28 after exposure. The vaccine should not be given in the gluteal area due to suboptimal response.

Rabies vaccines and HRIG should never be given in the same syringe or at the same site. Allergic reactions to the vaccine are rare, although local reactions (pruritus, erythema, tenderness) occur in about 25% and mild systemic reactions (headaches, myalgias, nausea) in about 20% of recipients. Adverse reactions to HRIG seem to be more frequent in women and rare in young children. The vaccine is commercially available or can be obtained through health departments.

Globally diverse anti-rabies vaccines are used. After Pasteur's research in the 19th century with increasingly virulent strains, the first licensed vaccine (1911) was inactivated and grown on bovine brain tissue. Subsequent vaccines were grown using duck or chick embryo cells but remained allergenic. Recent increasingly purified vaccines were grown on verocells, and a sixth-generation verocell rabies vaccine (VRVg) is under development. In some countries, the full spectrum of vaccines, from human diploid rabies (HDRV) to chromatographically purified rabies vaccine (CPRV) are available, whereas in others, the gamut is smaller and intradermal application of smaller vaccine doses at multiple sites and at different times is commonly practiced in an attempt to lower costs, and is deemed safe and effective by the World Health Organization.

In patients with history of past vaccination, the need for HRIG is eliminated (RIG is in short supply worldwide) but postexposure vaccination is still required. The vaccine should be given 1 mL in the deltoid twice (on days 0 and 3). Neither the passive nor the active form of postexposure prophylaxis is associated with fetal abnormalities and thus pregnancy is not considered a contraindication to vaccination.

Preexposure Immunization

Preexposure prophylaxis with three injections of HDCV intramuscularly (1 mL on days 0, 7, and 21 or 28) is recommended for persons at high risk for exposure: veterinarians (who should have rabies antibody titers checked every 2 years and be boosted with 1 mL intramuscularly or 0.1 mL intradermally if seronegative); animal handlers; laboratory workers; Peace Corps workers; and travelers with stays over 1 month to remote areas in endemic countries in Africa, Asia, and Latin America. An intradermal route is also available.

Intradermal preexposure prophylaxis (0.1 mL on days 0, 7, and 21 over the deltoid) is not available in the United States. Immunosuppressive illnesses and agents including corticosteroids as well as antimalarials—in particular chloroquine—may diminish the antibody response.

Treatment

Management requires intensive care with attention to the airway, maintenance of oxygenation, and control of seizures. Universal precautions are essential. The induction of coma by ketamine, midazolam, and supplemental barbiturates along with the use of amantadine and ribavirin, was reportedly helpful in one case but has failed to reproduce success in two subsequent cases. Corticosteroids are of no use.

Prognosis

If postexposure prophylaxis is given expediently, before clinical signs develop, it is nearly 100% successful in prevention of disease. Once the symptoms have appeared, death almost inevitably occurs after 7 days, usually from respiratory failure. Most deaths occur in persons with unrecognized disease who do not seek medical care or in individuals who do not receive postexposure prophylaxis.

When to Refer

Suspicion of rabies requires contact with public health personnel to initiate appropriate passive and active prophylaxis and observation of suspect cases.

When to Admit

- Respiratory, neuromuscular, or CNS dysfunction consistent with rabies.
- Patients with suspect rabies require initiation of therapy until the disease is ruled out in suspect animals, and this requires coordination of care based on likelihood of patient compliance, availability of inpatient and outpatient facilities, and response of local public health teams.

Arbovirus Encephalitides

Essentials of Diagnosis

- Fever, malaise, stiff neck, sore throat, and nausea and vomiting, progressing to stupor, coma, and convulsions.
- Signs of an upper motor neuron lesion (exaggerated deep tendon reflexes, absent superficial reflexes, pathologic reflexes, and spastic paralysis).
- Cerebrospinal fluid protein and opening pressure often increased, with lymphocytic pleocytosis.

General Considerations

The arboviruses are arthropod-borne pathogens that produce clinical manifestations in humans. The **mosquito-borne pathogens** that cause encephalitis include three togaviruses (causing Western, Eastern, and Venezuelan equine encephalitis), five flaviviruses (causing West Nile fever, St. Louis encephalitis, Japanese B encephalitis, dengue, and Murray Valley encephalitis), and bunyaviruses (the California serogroup of viruses, including the Lacrosse agent of California encephalitis). The **tick-borne** causes of encephalitis include the flavivirus of the Powassan encephalitis (northeastern United States and Canada) and tick-borne encephalitis virus of Europe; and the Colorado tick fever reovirus. Tick-borne encephalitis virus, Colorado tick fever, and the arboviruses associated with viral hemorrhagic fever (including dengue) are discussed below, and only those viruses causing primarily encephalitis in the United States will be discussed here.

Infection with West Nile virus was first identified in the United States in the New York City area in 1999. The virus spread rapidly, and current cases are reported throughout the continental United States. The homeless appear to be at increased risk for infection. In 2008, 1370 cases of WNV infection were reported to the CDC with more than half of them occurring in four states: California (411), Arizona (109), Mississippi (99), and Colorado (95). The highest incidences (> 100 per million population), however, were reported from Midwestern states (North Dakota, South Dakota, Nebraska, and Kansas).

Pathogen-specific reservoirs (typically small mammals or birds) are responsible for maintaining the encephalitis-producing viruses in nature. Birds are the main reservoir for West Nile virus and substantial avian mortality accompanies West Nile fever outbreaks. Outbreaks tend to occur in late summer and early fall. Real-time data at the county-level for sentinel cases (animal and human) of this infection in the United States can be found at http://diseasemaps.usgs.gov/.

Only dengue and Venezuelan equine encephalitis viruses produce viremias high enough to allow continued transmission to other mosquitoes and ticks. Human to human transmission of the other arboviruses are usually related to blood transfusion or organ transplantation. West Nile virus perinatal, transplacental, breast-feeding (rarely), laboratory, and possibly aerosol transmission can also occur. It is estimated that fever develops in 1 of 5 patients infected with West Nile virus, while severe neurologic disease presents in 1 of 150. St. Louis encephalitis and Powassan encephalitis occur among adults; Western equine encephalitis, Venezuelan equine encephalitis, and California encephalitis occur primarily among children, while West Nile fever and Eastern equine encephalitis are diseases of both children and adults.

Clinical Findings

Symptoms and Signs

The human incubation period for arboviral encephalitides is 2–14 days. Symptoms include fever, malaise, sore throat, headache, gastrointestinal upset, lethargy, and stupor progressing to coma. A nonpruritic maculopapular rash is variably present. Stiff neck and mental status changes are the most common neurologic signs. About 50% of hospitalized patients with West Nile virus infection in the United States have significant muscle weakness that may be initially confused with the Guillain–Barré syndrome. Acute flaccid (poliomyelitis-like) paralysis is seen in 10% of West Nile virus neuroinvasive disease and less commonly with the other arboviruses. Other signs include tremors, seizures, cranial nerve palsies, and pathologic reflexes. Myocarditis and hearing loss are also reported. The disease manifestations associated with West Nile virus infection are strongly age-dependent: the acute febrile syndrome and mild neurologic symptoms are more common in the young, aseptic meningitis and poliomyelitis-like syndromes are seen in the middle aged, and frank encephalopathy is seen in the elderly.

Laboratory Findings

The peripheral white blood cell count is variable. Cerebrospinal fluid protein is elevated; cerebrospinal fluid glucose is normal; there is usually a lymphocytic pleocytosis; and polymorphonuclear cells may predominate early. The diagnosis of arboviral encephalitides depends on serologic tests. Antibodies to arboviruses persist for life and the presence of IgG in the absence of a rising titer of IgM may indicate past exposure rather than acute infection. Documentation of a four-fold increase in acute/convalescence titers IgG or the presence of IgM antibodies is confirmatory. For West Nile virus, an IgM capture ELISA in serum or cerebrospinal fluid is almost always positive by the time the disease is clinically evident, and the presence of IgM in cerebrospinal fluid indicates neuroinvasive disease. These tests are commercially available but also obtainable through local or state health departments. Serologic tests specific for other arboviral encephalitides can be obtained through the CDC (http://www.cdc.gov/ncidod/dvbid/misc/specimen-submission.htm). Cross-reactivity exists among the different flaviviruses, so a plaque reduction assay may be needed to definitively distinguish between West Nile fever and St. Louis encephalitis. PCR assays (also available through the CDC) are less sensitive than serologic tests for the diagnosis of acute infections but are the preferred method for screening blood products and may be particularly useful in immunocompromised patients with abnormal antibody responses. CT scans of the brain usually show no acute disease, but MRI may reveal leptomeningeal, basal ganglia, thalamic, or periventricular enhancement.

Differential Diagnosis

Mild forms of encephalitis must be differentiated from aseptic meningitis, lymphocytic choriomeningitis, and nonparalytic poliomyelitis.

Severe forms of arbovirus encephalitides (Table 32–2) are to be differentiated from other causes of viral encephalitis (HSV, mumps virus, poliovirus or other enteroviruses, HIV), encephalitis accompanying exanthematous diseases of childhood (measles, varicella, infectious mononucleosis, rubella), encephalitis following vaccination (a demyelinating type following rabies, measles, pertussis), toxic encephalitis (from drugs, poisons, or bacterial toxins such as *Shigella dysenteriae* type 1), Reye syndrome, and severe forms of stroke, brain tumors, brain abscess, autoimmune processes such as lupus cerebritis, and intoxications. In the California Encephalitis Project, the cause for most cases of encephalitis was not identified.

Complications

Bronchial pneumonia, urinary retention and infection, prolonged weakness, and decubitus ulcers may occur. St. Louis encephalitis is reportedly associated with a postinfectious encephalomyelitis.

Prevention

No human vaccine is currently available for the arboviruses prevalent in North America, although yellow fever virus-based chimeric vaccines and recombinant vaccines are under development for West Nile virus. Mosquito control (repellents, protective clothing, and insecticides) is effective in prevention. Since 2003, all blood donations in the United States are screened with nucleic acid amplification tests for West Nile virus. Laboratory precautions are indicated for handling all these pathogens, in particular the West Nile virus.

A vaccine against Japanese B encephalitis is recommended for travelers to rural areas of East Asia, though the risk of disease acquisition among the exposed is estimated at only 1:1,000,000. This vaccination appears to provide some protection against West Nile virus (both agents are related flaviviruses).

Treatment

Although specific antiviral therapy is not available for most causative entities, vigorous supportive measures can be helpful. Such measures include reduction of intracranial pressure (mannitol) and monitoring of intraventricular pressure. The efficacy of corticosteroids in these infections is not established. Preliminary evidence that ribavirin was useful in West Nile virus encephalitis is not substantiated. Other therapeutic options such as IVIG or interferon- await confirmation of effectiveness.

Prognosis

Although most infections are mild or asymptomatic, the prognosis is always guarded, especially at the extremes of age. Homozygosity for a 32bp deletion in the gene coding for the chemokine receptor CCR5, associated with complete loss of function, predisposes to symptomatic West Nile virus infection. People with this mutation are resistant to HIV infection. The case fatality rate for West Nile virus neuroinvasive disease in the United States was

5.8% in 2008. Age older than 50 years is the most important risk factor for severe disease and death. Other risk factors for mortality include black race, chronic kidney disease, hepatitis C virus infection, and immunosuppression. Recovery of persons with severe neurologic compromise may take months. Sequelae of West Nile virus infection include a poliomyelitis-like syndrome, cognitive complaints, movement disorders, epilepsy, and depression; and they may become apparent late in the course of what appears to be a successful recovery. The prognosis is generally better for Western equine than for Eastern equine or St. Louis encephalitis.

[PMID: 18179388]

Lymphocytic Choriomeningitis

Essentials of Diagnosis

- "Influenza-like" prodrome of fever, chills, malaise, and cough, followed by meningitis with associated stiff neck.
- Aseptic meningitis with positive Kernig sign, headache, nausea, vomiting, and lethargy.
- Cerebrospinal fluid: slight increase of protein, lymphocytic pleocytosis (500–3000/mcL); low glucose in 25% of patients.
- Complement-fixing antibodies within 2 weeks.

General Considerations

The lymphocytic choriomeningitis virus is an arenavirus (related to the pathogen causing Lassa fever, discussed below) that causes infection of the CNS. The main reservoir for lymphocytic choriomeningitis virus is the house mouse. Other rodents (such as rats, guinea pigs, and even pet hamsters), monkeys, dogs, and swine are also potential reservoirs. Lymphocytic choriomeningitis virus is shed by the infected animal via nasal secretions, urine, and feces; transmission to humans probably occurs through aerosolized particles, direct contact, or animal bites. Human cases are most common in autumn. The virus is typically not spread person to person, though vertical transmission occurs, and lymphocytic choriomeningitis virus is an underrecognized neuroteratogen. Rare cases related to solid organ transplantation and autopsies of infected individuals are reported. Outbreaks tend to occur among persons with rodent exposure (eg, in the laboratory setting). Complications of clinical disease are rare.

This disease is principally confined to the eastern seaboard and northeastern states of the United States. Serologic evidence of past infection is present in 5% of adults in some urban areas of those regions and is higher in women, the elderly, and members of lower socioeconomic groups.

Clinical Findings

Symptoms and Signs

The incubation period is 8–13 days to the appearance of systemic manifestations and 15–21 days to the appearance of meningeal symptoms.

Symptoms are biphasic, with a prodromal illness characterized by fever, chills, headache, myalgia, cough, and vomiting, occasionally with lymphadenopathy and maculopapular rash. After 3–5 days, the fever subsides and recurs in 2–4 days with the meningeal phase, characterized by headache, nausea and vomiting, lethargy, and variably present meningeal signs. Obstructive hydrocephalus is a rare complication. Arthralgias can develop late.

Chorioretinitis also appears to be a sequela. Occasionally, a syndrome resembling the viral hemorrhagic fevers (see below) is described in transplant recipients of infected organs and in patients with lymphoma.

Laboratory Findings

Leukocytosis or leukopenia and thrombocytopenia may be present. Cerebrospinal fluid lymphocytic pleocytosis (total count is often 500–3000/mcL) may occur, with a slight increase in protein and normal to low glucose in at least 25%. The virus may be recovered from the blood and cerebrospinal fluid by mouse inoculation. Complement-fixing antibodies appear during or after the second week. Detection of specific IgM by ELISA is becoming widely used. Detection of lymphocytic choriomeningitis virus by PCR is available in research settings.

Differential Diagnosis

The influenza-like prodrome and latent period may distinguish this from other aseptic meningitides, and bacterial and granulomatous meningitis. A history of exposure to mice or other potential vectors is an important diagnostic clue.

Prevention

Pregnant women should be advised of the dangers to their unborn children inherent in exposure to rodents.

Treatment

Treatment is supportive. In the survivor of a transplant-associated outbreak, ribavirin (which is effective against other arenaviruses) was used successfully along with decreasing immunosuppression.

Prognosis

Fatalities are rare. The illness usually lasts 1–2 weeks, though convalescence may be prolonged. Congenital infection is more severe with about 30% mortality rate among infected infants, and more than 90% of survivors suffering long-term neurologic abnormalities.

Prion Diseases

Essentials of diagnosis

- Rare in humans.
- Cognitive decline.
- Myoclonic fasciculations, ataxia, visual disturbances, pyramidal and extrapyramidal symptoms.
- Variant disease in younger people with prominent psychiatric or sensory symptoms.
- Specific EEG patterns.

General Considerations

Several non-treatable neurodegenerative diseases are caused by communicable pathogens that contain protein but apparently lack nucleic acid as they are resistant to most procedures that modify it. They are called "prions" for *pr* oteinaceous *i* nfectious particles. These agents show slow replicative capacity and long latent intervals in the host. They induce the conformational change of a normal brain protein (prion protein; PrP^C) into an abnormal isoform (PrP^{Sc}) that accumulates and causes neuronal vacuolation (spongiosis), reactive proliferation of astrocytes and microglia and, in some cases, amyloid plaques. The term "transmissible spongiform encephalopathies" (TSE) refers to the spongiform appearance of the brain tissue observed in these conditions. A variety of animal diseases exhibit characteristics of TSE but those affecting humans include **classic Creutzfeldt–Jakob disease** (**cCJD**) and its **variant form** (vCJD), **kuru**, **Gerstmann-Sträussler-Scheinker syndrome** (GSS), and **fatal familial insomnia** (FFI). Infectious transmission of disease has only been described for vCJD, kuru and the iatrogenic form of cCJD (see below), whereas genetically determined mutations of PrP^C are the cause for the remainder. **Kuru** (characterized by cerebellar ataxia, tremors, dysarthria and emotional liability) was once prevalent in central New Guinea but now rare since the abandonment of cannibalism in the late 1950s. **FFI** occurs in kindreds (rarely sporadic) and **GSS** (ataxia and dysarthria, progressing to dementia and spastic paraparesis) is extremely rare. Only cCJD and vCJD will be further discussed here.

There are three forms cCJD: sporadic (80–85%), familial (15%), and iatrogenic (< 1%). There are no definitive risk factors for cCJD, and its annual incidence is about 1 in one million people per year. Familial cases are inherited in an autosomal dominant pattern with variable penetrance.

vCJD probably results from ingestion of beefsteak contaminated with neural tissue (brain, spinal cord) from livestock infected with **bovine spongiform encephalopathy (BSE)** ("mad cow disease"). A genetic variation in codon 129 of the PrP^C is highly prevalent in those patients affected. Since the first documented cases in Great Britain in the mid 1990s, more than 200 cases of vCJD have been reported with most cases reported from the United Kingdom. Only three cases of **vCJD** to date were reported in the United States (the last one in 2005), and all had documented former residence in the United Kingdom or Saudi Arabia. As of January 2009, only three cases of BSE were documented in the United States (from Washington, Texas, and Alabama), the last one in 2006. Canada in turn, has reported 15 cases to date, the last three in 2008. The risk for vCJD associated with the ingestion of beef products in these countries, thus, is very small. There is no animal-to-animal spread of BSE and milk and its derived products are not infected. Transmission through blood transfusions is documented in the United Kingdom.

Clinical Findings

A. Symptoms and Signs

The sporadic and familial cases of **cCJD** usually present in the sixth or seventh decade of life, whereas the iatrogenic form tends to occur in much younger patients. The typical clinical picture is dementia that progresses over several months, myoclonic fasciculations, ataxia, visual disturbances, pyramidal or extrapyramidal symptoms (or both), and akinetic mutism. **vCJD**, in contrast, usually affects younger people, the duration of disease is longer, and the clinical symptoms are unique (prominent psychiatric and sensory symptoms).

Laboratory Findings

The diagnosis of **CJD** should be considered in the proper clinical setting and in the absence of alternative diagnoses after routine investigations. Abnormalities in cerebrospinal fluid are subtle and rarely helpful. The detection of 14-3-3 protein in the cerebrospinal fluid is supportive of the diagnosis of **cCJD** but is not helpful in **vCJD.** Cerebrospinal fluid detection of other proteins like tau and neuron-specific enolase do not as yet show clinical utility. EEG typically shows a pattern of paroxysms with high voltages and slow waves in **cCJD,** and the MRI is characteristic for bilateral areas of increased signal intensity, predominantly in the caudate and putamen. **vCJD,** in contrast, shows diffusely abnormal but not diagnostic EEGs; and the MRI characteristically reveals hyperintensity of the posterior thalamus ("pulvinar sign"). The differentiation and definitive diagnosis of these diseases are ultimately established by neuropathologic confirmation.

Treatment & Prevention

There is no specific treatment for CJD and once symptoms appear, the infection invariably leads to death. Flupirtine (an analgesic drug) may slow cognitive decline but does not affect survival.

Iatrogenic cCJD can be prevented by limiting patient exposure to potentially infectious sources, which include human cadaveric growth hormones, gonadotrophins, corneal grafts, and dural grafts, and by restricting unnecessary exposure to stereotactic electroencephalography electrodes. Disinfection of equipment requires autoclaving at 15 psi for 1 hour, and disinfection of contaminated surfaces requires 5% hypochlorite or 0.1 N sodium hydroxide solution. Prevention of vCJD relies on surveillance of potentially infected livestock.

Progressive Multifocal Leukoencephalopathy

Progressive multifocal leukoencephalopathy (PML) is a rare demyelinating CNS disorder caused by the reactivation of JC virus (JCV; a polyomavirus). JCV infects children and has a reported seropositivity in adults of greater than 60%. The virus stays latent in the kidneys and lymphoid organs until reactivation. PML mainly occurs in adults with impaired cell-mediated immunity, especially AIDS patients but also in those with lymphoproliferative and myeloproliferative disorders, granulomatous, inflammatory and rheumatic diseases, solid and hematopoietic cell transplantation. Use of natalizumab, an anti-integrin monoclonal antibody used in multiple sclerosis and inflammatory bowel disease is associated with a reported incidence of PML of 1:1000 after 18 months of therapy. Case reports also implicate rituximab use. JCV causes lytic infection of oligodendocytes in the white matter and the symptoms presenting subacutely reflect the diverse areas of CNS involvement. Symptoms include altered mental status, aphasia, ataxia, hemiparesis or hemiplegia and visual field disturbances. Seizures occur in about 18%. Involvement of cranial nerves and cervical spine is rare.

PCR for JCV in cerebrospinal fluid is used for diagnosis in patients with compatible clinical and radiologic findings. MRI of the brain shows multifocal areas of white matter demyelination with no mass effect nor contrast enhancement. HAART for HIV improves survival as well as the clinical and radiographic features, although a small number of cases appear to worsen with immune restoration. Immune reconstitution syndromes do not alter mortality but are associated with a distinct form of PML called non-determined leukoencephalopathy associated with a distinct chemokine polymorphism. Significant neurologic sequelae to PML infections are the rule.

Decreasing immunosuppression in non-AIDS patients with PML (eg, transplant patients) is typically beneficial. Cidofovir may be beneficial in non-AIDS related cases; corticosteroids may be useful with immune reconstitution. Anecdotal responses to risperidone and mirtazapine are reported (The JC virus infects cells through serotonin receptors). Future reports will assess the role of small inhibitory RNAs.

Human T Cell Lymphotropic Virus (HTLV)

HTLV-1 and -2 are retroviruses. HTLV-1 is endemic to many regions in the world including the Caribbean, southern Japan (where more than 10% of the population is infected), sub-Saharan Africa, Latin America, Eastern Europe, Oceania, and the southeastern United States (where seroprevalence is most common among injection drug users). The virus is transmitted horizontally (sex), vertically (intrauterine, peripartum, and breast-feeding), and parenterally (injection drug use and blood transfusion).

The association of HTLV-1 with adult T cell lymphoma/leukemia (ATL) is well established. The lifetime risk of developing ATL among seropositive persons is estimated to be 3% in women and 7% in men, with an incubation period of at least 15 years. The mean age of diagnosis of ATL is 40–50 years in Central and South America but 60 years in Japan.

ATL clinical syndromes may be classified as chronic, acute (leukemic), smoldering, or lymphomatous. Presentation as a primary cutaneous tumor is also described and has a prognosis worse than the smoldering type. Clinical features of ATL include diffuse lymphadenopathy, maculopapular skin lesions that may evolve into erythroderma, organomegaly, lytic bone lesions, and hypercalcemia. Opportunistic infections, such as *Pneumocystis jiroveci* pneumonia and cryptococcal meningitis, are more common. HTLV seropositivity is associated with an increased risk of tuberculosis. The identification of HTLV-1 antibodies supports the diagnosis. The peripheral smear can show atypical lymphoid cells with basophilic cytoplasm and convoluted nuclei (flower cells) but the diagnostic standard is evidence of clonal integration of the proviral DNA genome into tumor cell. Management of ATL is similar to that for non-Hodgkin lymphoma. The use of interferon- , zidovudine, monoclonal antibodies or protein inhibitors is under evaluation.

HTLV-1 also causes HTLV-associated myelopathy (HAM; tropical spastic paraparesis). HAM develops in 0.3–4% of seropositive individuals and is more common in women. A chronic inflammation of the spinal cord leads to progressive motor weakness and symmetric spastic paraparesis or paraplegia with hyperreflexia. Bladder and sexual disorders, sensory disturbances, and constipation are also common.

HTLV-1 provirus load in peripheral blood mononuclear cells and in cerebrospinal fluid cells, and HTLV-1 mRNA load have all been proposed as markers of HAM risk and progression. HTLV positivity is associated with erythrocytosis and lymphocytosis (HTLV-II) and with thrombocytosis (HTLV-I and –II).

HAM is treated with a variety of immune-modulating agents (including corticosteroids) without consistent results. Combination of antiretrovirals does not show benefit. Interferon-a may be of some efficacy.

Patients infected with HTLV-1 show a risk of *Strongyloides stercoralis* hyperinfection. Other associations are with tuberculosis, crusted scabies, and infective dermatitis. Inflammatory states associated with HTLV-1 infection include arthropathy, polymyositis, uveitis, Sjögren syndrome, vasculitis, cryoglobulinemia, infiltrative pneumonitis, and ichthyosis.

HTLV-2 is no longer considered associated with hairy cell leukemia. HTLV-2 seropositivity is common in injection drug users. HTLV-2 causes a myelopathy that is milder and slower to progress than HAM.

HTLV-1/HIV coinfection is associated both with higher CD4 counts and a higher risk of HAM.

Screening of the blood supply for HTLV-1 is required in the United States. There is significant cross-reactivity between HTLV-1 and HTLV-2 by serologic studies, but PCR can distinguish the two.

Hemorrhagic Fevers

This diverse group of illnesses results from infection with one of several single-stranded RNA viruses (members of the families Arenaviridae, Bunyaviridae, Filoviridae, and Flaviviridae). Flaviviruses, such as the pathogens causing dengue and yellow fever (both with occasional hemorrhagic complications), are discussed in the following sections.

Modes of transmission are diverse. Lassa fever (an Old World arenavirus) is rodent associated and transmission usually occurs through aerosolized particles (from rodents or infected individuals) although contagion through direct contact with infected biologic fluids or tissues is also documented. Similar modes of transmission are assumed for Junin hemorrhagic fever and other diseases due to New World Arenaviridae. Ebola fever and Marburg fever (outbreaks in the Democratic Republic of Congo from 1998 to 2000 and in Angola from 2004 to 2005) are due to filoviruses with unknown vectors. Bats are the suspected reservoir for Ebola and Marburg viruses, and infection with the latter is associated with mining in the Congo. The bunyaviruses include the tick-borne Crimean-Congo hemorrhagic fever, the mosquito-borne Rift Valley fever (cause of a major outbreak in Saudi Arabia in 2000–2001 involving over 800 persons), and the hantaviruses (associated with rodent exposure and discussed separately below). Hospital-associated transmission of Crimean-Congo hemorrhagic fever is well documented in Iran.

Clinical Findings

Symptoms and Signs

The incubation period can be as short as 2 days for the Rift Valley fever or as long as 21 days for Lassa fever. The clinical symptoms in the early phase of a viral hemorrhagic fever are very similar, irrespective of the causative virus, and resemble a flu-like illness or gastroenteritis. Hepatitis is common.

The late phase is more specific and is characterized by organ failure, persistent leukopenia, altered mental status, and hemorrhage. Exanthemas and mucosal lesions can occur. Adrenal dysfunction is a common sequela and a cause for the development of the late-stage shock associated with these infections. The case-fatality rate ranges from 5% to 30% and may be as high as 90% in Ebola fever. The convalescence period can be long and complicated. There is no evidence of chronic infection among survivors.

Laboratory Findings

Laboratory features usually include thrombocytopenia, leukopenia, (although with Lassa fever leukocytosis is noted), anemia, increased hematocrit, oftenly elevated liver function tests, and findings consistent with disseminated intravascular coagulation (although less prominently in Lassa fever). Urinalysis can reveal proteinuria and hematuria.

Special care should be taken for handling clinical specimens of suspected cases. Laboratory personnel should be warned about the diagnostic suspicion and the CDC must be contacted for guidance (Special Pathogens Branch, 404-639-1115). Diagnosis may be made by growing the virus from blood obtained early in the disease, antigen detection (by ELISA), nucleic acid amplification (PCR techniques), or by demonstration of a significant specific fourfold or greater rise in antibody titer. Detection of Ebola virus antigen in oral fluid samples by ELISA and RT-PCR may be possible; sample collection in this manner will be useful since certain ethnic customs prohibit blood collection. These tests are generally available only through the CDC.

Differential Diagnosis

The differential diagnosis for hemorrhagic fever includes meningococcemia or other septicemias, Rocky Mountain spotted fever, dengue, typhoid fever, and malaria. The likelihood of acquiring hemorrhagic fevers among travelers is low.

Treatment

Patients should be placed in private rooms with standard contact and droplet precautions. Barrier precautions to prevent contamination of skin or mucous membranes should also be adopted by the caring personnel. Airborne precautions should be considered in patients with significant pulmonary involvement or undergoing procedures that stimulate cough.

Certain arenaviruses (the Lassa pathogen, Junin virus in its viscerotropic phase, Machupo virus) and bunyaviruses (the Congo-Crimean hemorrhagic fever and Rift Valley fever pathogens) respond to oral ribavirin if it is started promptly: 30 mg/kg as loading dose, followed by 16 mg/kg every 6 hours for 4 days and then 8 mg/kg every 8 hours for 3 days. The filoviruses and the flaviviruses do not respond to ribavirin. Live attenuated vaccines are available for Junin hemorrhagic fever and the Rift Valley fever, and they are under study for the Crimean-Congo hemorrhagic fever, Ebola, and Marburg viruses. In addition, recombinant vaccines are under development for most of these pathogens (including the Lassa fever virus but not the Junin hemorrhagic fever virus). Therapeutic interventions that target the hematologic system are either ineffective or only marginally effective.

When to Admit

- Persons with symptoms compatible with those of any hemorrhagic fever and who have traveled from a possible endemic area should be isolated for diagnosis and symptomatic treatment.
- Isolation is particularly important because diseases due to some of these agents, such as Ebola virus, are highly transmissible and carry a mortality rate of 50–90%.

Dengue

Essentials of Diagnosis

- Exposure 7–10 days before onset.
- Sudden onset of high fever, chills, severe myalgias and arthralgias, headache, sore throat, and depression.
- Biphasic fever curve: initial phase, 3–7 days; remission, few hours to 2 days; second phase, 1–2 days.
- Biphasic rash: evanescent, then maculopapular, scarlatiniform, morbilliform, or petechial changes from extremities to torso.
- Leukopenia and thrombocytopenia in the hemorrhagic form.

General Considerations

Dengue is due to a flavivirus transmitted by the bite of the *Aedes* mosquito. It may be caused by one of four serotypes widely distributed globally between the tropics of Capricorn and Cancer. An estimated 50–100 million cases of dengue fever and several hundred thousand cases of dengue hemorrhagic fever occur each year. The incubation period is 3–15 days (usually 7–10 days). When the virus is introduced into susceptible populations, usually by viremic travelers, epidemic attack rates range from 50% to 70%. Dengue is endemic in the lower Rio Grande Valley and adjacent border towns, with 40% of Brownsville, Texas residents showing serologic evidence of past infection and the virus being detected in mosquito larvae among 30% of households.

Severe epidemics of dengue hemorrhagic fever (serotype 3) occurred over the past 20 years in East Africa, Sri Lanka, and Latin America. In general, the more advanced forms of disease (hemorrhagic fever and shock) occur less often in the Americas than in Asia. In 2005, the first outbreak of dengue hemorrhagic fever in the continental United States was documented. The outbreak was binational and involved more than 6000 persons in Brownsville, Texas and Matamoros, Mexico with primarily serotype 2. Dengue is the second most common cause of fever (after malaria) in the traveler returning from developing countries. Nosocomial (via needlesticks or mucocutaneous exposure) and vertical transmission occur rarely.

Clinical Findings

Symptoms and Signs

Dengue infection may range from asymptomatic to severe hemorrhagic fever and fatal shock (**dengue shock syndrome**). Dengue fever is usually a nonspecific, self-limited biphasic febrile illness. More than half of infected children are asymptomatic. The illness is more severe and begins more suddenly in adults. After an incubation period of 4–5 days, there is a sudden onset of high fever, chills, and "break bone" aching of the head, back, and extremities accompanied by sore throat, prostration, and malaise. There may be conjunctival redness. Initially, the skin appears flushed or blotched, but 3–4 days after the lysis of the fever, a maculopapular rash, which spares palms and soles, appears in over 50% of cases. As the rash fades, localized clusters of petechiae on the extensor surface of the limbs become apparent. Hepatitis frequently complicates dengue fever.

Dengue hemorrhagic fever usually affects children living in endemic areas and is most likely to occur in secondary infections and in infections with serotype 2. A few days into the illness, signs of hemorrhage such as ecchymoses, gastrointestinal bleeding, and epistaxis appear. Symptoms found more often among the hemorrhagic fever subset of patients include restlessness, epistaxis, and abdominal pain.

A subset of patients, often with secondary infection, may progress to dengue shock syndrome in which acute fever, hemorrhagic manifestations, and marked capillary leak are prominent; the latter manifests as pleural effusions and ascites, and there is a tendency for shock to develop. While the infection is difficult to distinguish from malaria, yellow fever, or influenza, the rash makes dengue far more likely. Continuous abdominal pain with vomiting, bleeding, a decrease in the level of consciousness, and hypothermia should raise concern about dengue shock syndrome. A history of travel to a dengue-endemic area within 14 days of symptom onset is helpful for diagnosis.

Laboratory Findings

Leukopenia is characteristic, and elevated transaminases are found frequently in dengue fever. Thrombocytopenia, increased fibrinolysis, and hemoconcentration occur more often in the hemorrhagic form of the disease. Liver function abnormalities are nearly universal. The nonspecific nature of the illness mandates laboratory verification for diagnosis, usually with IgM and IgG ELISAs after the febrile phase. Virus may be recovered from the blood during the acute phase. PCR or detection of the specific viral protein NS1 by ELISA may be diagnostic during the first few days of infection. Immunohistochemistry for antigen detection in tissue samples can also be used. Chest radiographs in dengue hemorrhagic fever show infiltrates and effusions, which follow the course of laboratory abnormalities.

Complications

Usual complications include pneumonia; bone marrow failure; hepatitis; iritis, retinal hemorrhages, and maculopathy; orchitis; and oophoritis. Depression and chronic fatigue, occurring more often in older women, are also reported. Neurologic complications, such as encephalitis, Guillain–Barré syndrome, and transverse myelitis, are less common. Bacterial superinfection occurs more commonly with advanced age, higher fever, gastrointestinal bleeding, kidney disease, and altered consciousness.

Prevention

Available prophylactic measures include control of mosquitoes by screening and insect repellents, particularly during early morning and late afternoon exposures.

Tetravalent live attenuated vaccines and genetically modified chimeric virus vaccines are under study and entering clinical trials.

Treatment

Treatment entails the appropriate use of volume support (with Ringer lactate in moderately severe shock and colloids in more severe cases), blood products, and pressor agents, and acetaminophen rather than nonsteroidal anti-inflammatory drugs for analgesia. Activities are gradually restored during prolonged convalescences. Endoscopic therapy is useful in evaluating and managing gastrointestinal hemorrhage, although injection therapy with sclerosing agents is not beneficial in most dengue hemorrhagic states. Platelet counts do not usefully predict clinically significant bleeding. Platelet transfusions, however, should be considered for severe thrombocytopenia (< 10,000/mL) or when there is evidence of bleeding. Monitoring for hemoconcentration may help in anticipating the complications of dengue hemorrhagic fever or shock syndrome.

Prognosis

Fatalities are rare but do occur, especially during epidemic outbreaks, with occasional patients dying of fulminant hepatitis. Convalescence for most patients is slow.

Hantaviruses

Hantaviruses are rodent-borne enveloped RNA bunyaviruses with several distinct serotypes. These differ in rodent hosts, geographic distribution, and degree of pathogenicity for humans. They cause two major clinical syndromes: **hemorrhagic fever** (discussed above) and the **hantavirus pulmonary syndrome** (HPS). Each year, over 150,000 cases of these two syndromes occur globally, with HPS being far less common. Aerosols of virus-contaminated rodent urine and perhaps feces are thought to be the main vehicle for transmission to humans. The ubiquity of hantaviruses is recognized, with descriptions of infections from North and South America (New World hantaviruses) and additional infections from Europe and Asia (Old World hantaviruses). The Hantaan serotype viruses cause severe hemorrhagic fever with renal syndrome and are found primarily in Korea, China, and eastern Russia. The Seoul viruses produce a less severe form and are found primarily in Korea and China. The Puumala and Dobrava viruses are found in Scandinavia and Europe and are associated with a milder form of the syndrome, nephropathia epidemica, which usually presents with fever, headache, gastrointestinal symptoms, and impaired kidney function.

The Sin Nombre (Muerto Canyon, Four Corners) virus is the most common hantavirus infection in the United States and is the chief North American virus responsible for HPS; it is usually seen in the southwestern United States. Between 1993 and 2006, 438 cases were reported in 32 states in an area roughly coterminous with the distribution of plague. Outbreaks of HPS with other hantavirus types are also reported from Central and South America. HPS (the mean incubation period for which is 18 days) begins as a nonspecific febrile illness followed by a severe increase in pulmonary vascular permeability associated with a CD8 immune response, leading to respiratory failure, and rapid progression to a shock-like state. Laboratory features include thrombocytopenia, hemoconcentration, leukocytosis (with abnormal lymphocytes and immature myeloid cells), and elevated lactate dehydrogenase and transaminases. Clinical similarities, including a propensity toward kidney involvement exist between the New World hantaviruses and their Old World counterparts.

Diagnosis can be made serologically, with most patients having both IgM and IgG antibodies at the time of presentation; by immunohistochemical staining; or by PCR amplification of viral tissue DNA (the agents may be isolated from blood or saliva). A viral load assay correlates with severity of disease among patients with HPS caused by the Sin Nombre virus.

Treatment is mainly supportive. Intravenous ribavirin has been used with some success in hemorrhagic fever with renal syndrome (Hantaan virus), but studies in HPS suggest it is not effective. Cardiorespiratory support with pressors and sometimes extracorporeal membrane oxygenation may be considered. Because infection is thought to occur by inhalation of rodent wastes, prevention is aimed at eradication of rodents in houses and avoidance of exposure to rodent excreta in rural settings, including forest service facilities.

Yellow Fever

Essentials of Diagnosis

- Endemic area exposure (tropical South and Central America, Africa, but not Asia).
- Sudden onset of severe headache, aching in legs, and tachycardia.
- Brief (1 day) remission, followed by bradycardia, hypotension, jaundice, hemorrhagic tendency.
- Proteinuria, leukopenia, bilirubinemia, bilirubinuria.
- Rare and potentially fatal reactions to vaccination.

General Considerations

Yellow fever is a zoonotic flavivirus infection transmitted by *Aedes* and jungle mosquitoes. It occurs in an urban and jungle cycle in Africa and in a jungle cycle in South America (where genetic studies suggest it arose through the slave trade 300–400 years ago). Epidemics have extended far into the temperate zone during warm seasons.

The mosquito transmits the infection by first biting an individual having the disease and then biting a susceptible individual after the virus has multiplied within the mosquito's body. The incubation period in humans is 3–6 days. Adults and children are equally susceptible, though attack rates are highest among adult males because of their work habits. Between 5% and 50% of infections are asymptomatic.

Clinical Findings

Symptoms and Signs

Mild form

Symptoms are malaise, headache, fever, retroorbital pain, nausea, vomiting, and photophobia. Relative bradycardia, conjunctival injection, and facial flushing may be present.

Severe form

Severe illness develops in about 15%. Initial symptoms are similar to the mild form, but a brief fever remission lasting hours to a few days is followed by a "period of intoxication" manifested by fever and relative bradycardia (Faget sign), hypotension, jaundice, hemorrhage (gastrointestinal, nasal, oral), and delirium that may progress to coma.

Laboratory Findings

Leukopenia occurs, although it may not be present at the onset. Kidney disease with proteinuria is present, sometimes as high as 5–6 g/L, and usually disappears completely with recovery. Levels of liver enzymes and bilirubin can be remarkably abnormal with the levels of aspartate aminotransferase (AST) usually doubling those of alanine aminotransferase (ALT). Prothrombin time may be elevated as well. Serologic diagnosis is primarily by measurement of IgM by capture ELISA during the acute and convalescent phases. Viral culture is possible and has been used in epidemic settings. Rapid test involving PCR protocols and immunoassays of monoclonal antibodies against circulating viral antigens are becoming more widely available.

Differential Diagnosis

It may be difficult to distinguish yellow fever from hepatitis, malaria, leptospirosis, louse-borne relapsing fever, dengue, and other hemorrhagic fevers on clinical evidence alone. Albuminuria is a constant feature in yellow fever patients and its presence helps differentiate yellow fever from other viral hepatitides. Serologic confirmation is often needed.

Prevention

Transmission is prevented through mosquito control. Live virus vaccine is highly effective and should be provided for immunocompetent persons over 9 months of age living in or traveling to endemic areas. Revaccination is recommended every 10 years for persons with continued exposure. Vaccine-induced reactions, including neurotropic (encephalitis-like syndrome) and viscerotropic (resembling yellow fever) diseases are reported (particularly among patients of 60 years or older and patients with thymic dysfunction; the former should probably not be vaccinated and the latter definitely not be vaccinated). The safety of the vaccine in pregnant patients is not verified, and pregnant women should, if possible, defer travel to endemic areas (see Chapter 30: Common Problems in Infectious Diseases & Antimicrobial Therapy). Eradication is difficult because of the sylvatic cycle (mainly maintained by non-human primates).

Treatment

No specific antiviral therapy is available. Treatment is directed toward symptomatic relief and management of complications. If not in an endemic area, the patient should be isolated from mosquitoes to prevent transmission, since blood in the acute phase is potentially infectious.

Prognosis

The mortality rate of the severe form is 20–50%, with death occurring most commonly between the sixth and the tenth days. In survivors, the temperature returns to normal by the seventh or eighth day. The prognosis in any individual case is guarded at the onset, since sudden changes for the worse are common. Intractable hiccups, copious black vomitus, melena, anuria, jaundice, and elevated AST are unfavorable signs. Convalescence is prolonged, including 1–2 weeks of asthenia. Infection confers lifelong immunity to those who recover.

Tick-Borne Encephalitis

Essentials of Diagnosis

- Flaviviral encephalitis found in Eastern, Central, and occasionally Northern Europe and Asia.

- Transmitted via ticks or ingestion of unpasteurized milk.
- Long-term neurologic sequelae occur in 2–25% of cases.
- Therapy is largely supportive.
- Prevention is based on avoiding tick exposure, pasteurization of milk, and vaccination.

General Considerations

Tick-borne encephalitis (TBE) is a flaviviral infection caused by TBE virus. This infection is endemic in Russia and in eastern and central Europe, but cases are also well recognized in western Europe, China, and Japan. An estimated 10,000 to 12,000 cases occur each year in parts of Europe and the Baltic, with annual increases thought to be a function of increased recognition, climatic changes, and personal or social habits. TBE occurs predominantly in the late spring through fall. It is usually a consequence of exposure to infected ticks, although unpasteurized milk from viremic livestock is also a recognized form of transmission. The incubation period is 7–14 days for tick-borne exposures but only 3–4 days for milk ingestion. The principal reservoirs for TBE virus are small rodents; humans are an accidental host. The vectors for most cases are *Ixodes ricinus* (most of Europe, including Turkey, Iran, and the Caucasus) and *Ixodes persulcatus* (in the belt from eastern Europe to China and Japan).

Clinical Findings

Symptoms and Signs

Most cases are subclinical and many resemble a flu-like syndrome. There are two variants of clinical presentation: the Western subtype occurs mainly in the fall and is most severe among the elderly, and the Eastern subtype is more severe among children.

Western subtype disease is biphasic in which after 2–10 days of fever (usually with malaise, headache, and myalgias), a 1–21 day symptom-free interval leads to a second phase with resumed fevers followed by neurologic symptoms. Eastern subtype disease is progressive without an asymptomatic interval. The neurologic manifestations range from febrile headache (accounting for up to 50% of Eastern subtype cases) to aseptic meningitis and encephalitis with or without myelitis (preferentially of the cervical anterior horn) and spinal paralysis (usually flaccid). A myeloradiculitic form can also develop but is less common. Double infection with *Borrelia burgdorferi* (the agent if Lyme disease; transmitted by the same tick vector) may result in a more severe disease. Homozygosity for a 32bp deletion in the gene coding for the chemokine receptor CCR5, producing its complete loss of function, predisposes to severe disease. People with this mutation are, however, naturally resistant to HIV infection and CCR5 is the target of blockage by newer antiretroviral medications (eg, maraviroc and vicriviroc). Mortality in TBE is usually a consequence of brain edema or bulbar involvement.

Diagnosis

Leukocytosis and neutrophilia are common. Abnormal cerebrospinal fluid findings include a pleocytosis that may persist for up to 4 months. Neuroimaging shows hyperintense lesions in the thalamus, brainstem, and basal ganglia. TBE virus IgM and IgG are detected by ELISA techniques when neurologic symptoms occur. Cross-reactivity with other flaviviruses or a vaccinated state (see below) may require confirmation by detection of TEB virus–specific antibodies in cerebrospinal fluid. RT-PCR of blood (at earlier stages of the disease) or cerebrospinal fluid can sometimes, if available, assist with the diagnosis.

Complications

The main sequela of disease is paresis, which occurs in up to 10% of Western and up to 25% of Eastern subtype disease. Other causes of long-term morbidity include protracted cognitive dysfunction and persistent spinal nerve paralysis. The postencephalitic syndrome, characterized by headache, difficulties concentrating, balance disorders, dysphasia, hearing defects, and chronic fatigue, occurs with both subtypes. A progressive motor neuron disease may occur with the Eastern subtype.

Differential Diagnosis

The differential diagnosis includes other causes of aseptic meningitis such as enteroviral infections, herpes simplex encephalitis, and a variety of tick-borne pathogens including tularemia, the rickettsial diseases, babesiosis, Lyme disease, poliomyelitis (no longer reported from Eastern Europe) and other flaviviral infections.

Prevention

There are two inactivated TBE virus vaccines for adults and two vaccines for children licensed in Europe. Their effectiveness is about 99% when properly administered. The initial vaccination schedule requires 1 year with boosters every 3–5 years. Other prevention recommendations include avoidance of tick exposure and pasteurization of milk.

Treatment

Therapy is largely supportive. Some clinicians believe corticosteroids may be useful, although no controlled clinical trials exist.

(CCR5) gene is associated with tickborne encephalitis. J Infect Dis. 2008 Jan 15;197(2):266–9. [PMID: 18179389]

Lindquist L et al. Tick-borne encephalitis. Lancet. 2008 May 31;371(9627):1861–71. [PMID: 18514730]

Colorado Tick Fever

Essentials of Diagnosis

- Onset 1–19 days (average, 4 days) following tick bite.
- Fever, chills, myalgia, headache, prostration.
- Leukopenia, thrombocytopenia.
- Second attack of fever after remission lasting 2–3 days.

General Considerations

Colorado tick fever is a reportable acute reovirus infection transmitted by *Dermacentor andersoni* bites. The disease is limited to the western United States and Canada and is most prevalent during the tick season (March to November). There is a discrete history of tick bite or exposure in 90% of cases. The virus infects the marrow erythrocyte precursors, leading to viremia lasting the life span of the infected red cells. Blood transfusions can be a vehicle of transmission.

Clinical Findings

Symptoms and Signs

The incubation period is 3–6 days. The onset is usually abrupt with fever (to 38.9–40.6 °C), sometimes with chills. Severe myalgia, headache, photophobia, anorexia, nausea and vomiting, and generalized weakness are prominent. Physical findings are limited to an occasional faint rash. The acute symptoms resolve within a week. The remission is followed in 50% of cases by recurrent fever and a full recrudescence lasting 2–4 days. In an occasional case there may be three bouts of fever.

The differential diagnosis includes influenza, Rocky Mountain spotted fever, numerous other viral infections and, in the right setting, relapsing fevers.

Laboratory Findings

Leukopenia (2000–3000/mcL) with a shift to the left and atypical lymphocytes occurs, reaching a nadir 5–6 days after the onset of illness. Thrombocytopenia may occur. Viremia may be demonstrated by inoculation of blood into mice or by fluorescent antibody staining of the patient's red cells (with adsorbed virus). An RT-PCR assay may be used to detect early viremia. Detection of IgM by capture ELISA or plaque reduction neutralization is possible after 2 weeks from symptom onset and is the most frequently used diagnostic tool.

Complications

Aseptic meningitis (particularly in children), encephalitis, and hemorrhagic fever occur rarely. Malaise may last weeks to months. Fatalities are very rare. There is one reported case of spontaneous abortion and multiple congenital anomalies associated with Colorado tick fever

Treatment

No specific treatment is available. Ribavirin has shown efficacy in an animal model. Antipyretics are used, although aspirin should be avoided. Tick-avoidance is the best prevention.

Prognosis

The disease is usually self-limited and benign.

Romero JR et al. Powassan encephalitis and Colorado tick fever. Infect Dis Clin North Am. 2008 Sep;22(3):545–59. [PMID: 18755390]

Chikungunya Fever

Chikungunya ("that which bends up" in Bantu) is a flaviviral infection transmitted to humans by *Aedes aegypti* and *Aedes albopictus*. While historically limited to tropical Africa and Asia, a major ongoing outbreak starting in 2004 spread the disease to the Indian subcontinent and to northeastern Italy, with attack rates of around 50% in some regions. Travelers return often viremic from these areas. The endemicity of *A aegypti* in the Americas and the introduction of *A albopictus* into Europe and the New World raise the concerns of a global extension of the epidemic.

Clinical Findings

Symptoms and Signs

After an incubation period of 1–12 days (average 2–4), there is an abrupt onset of fever; headache; intestinal complaints; myalgias; and arthralgias/arthritis affecting small, large, ans axial joints. The simultaneous involvement of more than 10 joints and the presence of tenosynovitis (especially in the wrist) are characteristic. The stooped posture of patients gives the disease its name. Joint symptoms persists for 4 months in 33% and linger for years in about 10%. A centrally distributed pruritic maculopapular rash is reported in 50% of the patients, but it can be bullous with sloughing in children. Facial edema and localized petechiae are reported. Meningoencephalitis is occasional and hemorrhagic fever-like presentation exceptional. Coinfection with other respiratory viruses is common. Death is rare and usually related to underlying comorbidities.

Laboratory Findings

Diagnosis is made epidemiologically and clinically. Mild leukopenia occurs as does thrombocytopenia, which is seldom severe. Elevated inflammatory markers do not correlate with the severity of arthritis. Radiographs of affected joints are normal.

Serologic confirmation requires elevated IgM titers or fourfold increases in convalescent IgG levels. RT-PCR and culture techniques (viral isolation in insect or mammalian cell lines or by inoculation of mosquitoes or mice) are seldom available. Suspected cases in the United States should be promptly reported to public health authorities including the CDC Arboviral Diseases Branch, 970-221-6400. The differential includes other tropical febrile diseases, such as malaria or dengue.

Treatment

Treatment is largely supportive with nonsteroidal anti-inflammatory drugs. Chloroquine may be useful for managing refractory arthritis. No vaccine is available, and prevention relies on avoidance of the mosquito vectors. Vertical transmission is documented, but teratogenicity is not established.

Simon F et al. Chikungunya: a paradigm of emergence

and globalization of vector-borne diseases. Med Clin North Am. 2008 Nov;92(6):1323–43. [PMID: 19061754]

Respiratory Syncytial Virus & Other Paramyxoviruses

General Considerations

Respiratory syncytial virus (RSV) is a paramyxovirus that causes annual outbreaks, in winter and early spring, of pneumonia, bronchiolitis, and tracheobronchitis, with the majority of cases occurring in the very young. Risk factors include prematurity, low birth weight, younger age (especially younger than 6 months), bronchopulmonary dysplasia, congenital heart disease, later birth order, and day care exposure. Reinfections are common but usually milder. In older children and adults, RSV infection is typically manifested as an upper respiratory tract infection and tracheobronchitis. The virus enters through contact with mucosal surfaces, as the eye or nose. The average incubation period is 5 days. RSV infection in children has been associated with persistence of airway reactivity later in life in some studies.

In immunocompromised patients, such as bone marrow transplant recipients, serious pneumonia can occur and outbreaks with a high mortality rate (> 70%) are reported. RSV infection is also an important illness in elderly and other high-risk adults (eg, those with chronic heart or lung diseases).

Other paramyxoviruses important in human disease include human metapneumovirus and parainfluenza virus. **Human metapneumovirus** is less common and less pathogenic than RSV. It appears to cause bronchiolitis; croup; exacerbation of pneumonia; and pneumonia during the winter and spring among slightly older children and is responsible for lower respiratory tract infections among immunocompromised and elderly adults. **Parainfluenza viruses,** the most common cause of croup**,** also causes respiratory tract infections in the very young, the elderly, the immunocompromised, and those with chronic illnesses. **Bocavirus** infections are discussed under parvoviruses.

Clinical Findings

Symptoms and Signs

In RSV bronchiolitis, proliferation and necrosis of bronchiolar epithelium develop, producing obstruction from sloughed epithelium and increased mucus secretion. Signs include low-grade fever, tachypnea, and wheezes. Apnea is a common presenting symptom. Hyperinflated lungs, decreased gas exchange, and increased work of breathing are present. In children, RSV is a common cause of acute and recurrent otitis media. RSV-confirmed bronchiolitis in children under age 13 is associated with the development of asthma. RSV pneumonia is a serious condition in the elderly and debilitated patient as well as in the immunocompromised person.

Laboratory Findings

A rapid diagnosis of RSV infection is made by viral antigen identification of nasal washings using an ELISA or immunofluorescent assay. Culture of nasopharyngeal or lower respiratory tract secretions remain the standard of diagnosis, although PCR is increasingly used. Coinfection with bacteria is relatively uncommon in industrialized countries. Coinfection with *B pertussis* and other viruses occurs in a subset of patients hospitalized for RSV infection. Detection of parainfluenza virus usually requires culture, but tests for rapid detection of viral antigens with immunofluorescence or ELISA, and PCR techniques are also available. Human metapneumovirus is best diagnosed by PCR.

Treatment

Treatment of RSV consists of supportive care, including hydration, humidification of inspired air, and ventilatory support as needed. Neither bronchodilating agents nor corticosteroids have demonstrated efficacy in bronchiolitis although individual patients with significant bronchospasm or history of asthma might respond to them. Use of nebulized ribavarin might be considered in some high risk and very sick children (eg, immunosuppressed, those with underlying pulmonary or congenital heart conditions, and those with severe respiratory compromise) but the evidence of its efficacy is not well documented and this therapy is expensive and cumbersome. There is no evidence that macrolides are beneficial to infants or children with lower respiratory tract disease caused by RSV.

Ribavirin can also be considered in high-risk adults, such as those with a history of bone marrow transplantation. Pregnant women, including hospital staff, should avoid ribavirin exposure. Therapy with surfactant lacks evidence to make recommendations on its use. Passive immunotherapy has no role in treating acute infections in children. The combination of hyperimmune RSV immunoglobulin G (RSVIG) and ribavarin appears to be beneficial in uncontrolled studies of infected adult bone marrow transplant patients. In the United States, RSVIG is no longer available and has been replaced with palivizumab, a monoclonal RSV antibody. Administration of palivizumab prophylactically (parenterally at 15 mg/kg monthly during the season of high transmission) to infants with high-risk factors, such as congenital heart disease, is well recommended. Future studies may entail the use of small inhibitory RNA molecules and of newer generation monoclonal antibodies, such as motavizumab.

Live attenuated vaccines fail to show significant clinical protection or immunogenicity in adults and their use in infants raises safety concerns. Prevention in hospitals entails rapid diagnosis, handwashing, contact isolation, and perhaps passive immunization. Therapeutic modalities for human metapneumovirus and parainfluenzavirus infections under investigation include ribavirin administration. The use of conjugated pneumococcal vaccination appears to decrease the incidence of concomitant pneumonia associated with viral infections in children in some countries.

Influenza

Essentials of Diagnosis

- Cases usually in epidemic pattern.
- Abrupt onset with fever, chills, malaise, cough, coryza, and myalgias.
- Aching, fever, and prostration out of proportion to catarrhal symptoms.
- Leukopenia.

General Considerations

Influenza (an orthomyxovirus) is a highly contagious disease transmitted by the respiratory route. In contrast to RSV and rhinoviruses, transmission occurs primarily by droplet nuclei rather than fomites or large particle aerosols. There are three types of influenza viruses. While type A can infect a variety of mammals (humans, swine, horses, etc) and birds, types B and C almost exclusively infect humans. Type A viruses are further divided into subtypes based on the hemagglutinin (H) and the neuraminidase (N) expressed in their surface. There are 16 subtypes of hemagglutinin and 9 subtypes of neuraminidase. Annual epidemics usually appear in the fall or winter (although sporadic cases occur as summer outbreaks in northern areas such as Alaska); they affect 10–20% of the global population on average each year and are rarely the result of frequent minor antigenic variations of the virus, or antigenic drift, which are more common in influenza A virus. On the other hand, pandemics—associated with higher mortality—appear at longer (3–5 decades) and varying intervals as a consequence of a major genetic reassortment of the virus (antigenic shift) or the mutation of an animal virus that adapts to the human (as with the avian-origin (H5N1) pandemic virus of 1918). Currently, the main circulating influenza viruses are the human-origin A (H1N1) and (H3N2) subtypes, as well as type B. A novel swine-origin influenza A (H1N1) virus of pandemic potential emerged in Mexico in March of 2009 and quickly spread through North America and elsewhere. In addition, a highly pathogenic avian (H5N1) subtype that caused occasional human infections in Asia and Europe over the last decade is still cause of ongoing global concern. The infections with influenza viruses of human origin will be discussed here, whereas those due to avian- and swine-origin viruses will be covered in the next sections.

Clinical Findings

Symptoms and Signs

Human-origin influenza viruses of antigenic types A and B produce clinically indistinguishable infections, whereas type C usually causes a minor illness. Typically, the infection has an incubation period is 1–4 days. In unvaccinated persons, typical uncomplicated influenza often begins abruptly. Symptoms include fever, chills, malaise, myalgias, substernal soreness, headache, nasal stuffiness, and occasionally nausea. Fever lasts 1–7 days (usually 3–5). Coryza, nonproductive cough, and sore throat are present. Elderly patients may present with only lassitude and confusion, often without fever or respiratory symptoms. Signs include mild pharyngeal injection, flushed face, and conjunctival redness. Moderate enlargement of the cervical lymph nodes may be observed. The presence of fever (> to 38.2 °C) and cough during influenza season is highly predictive of influenza infection in those older than 4 years of age.

Laboratory Findings

Leukopenia is common, but leukocytosis can occur. Proteinuria may be present. The virus may be isolated from throat swabs or nasal washings by inoculation of embryonated eggs or cell cultures. Rapid immunofluorescence assays and enzyme immunoassays for detection of influenza antigens from nasal or throat swabs are becoming widely available; however, their sensitivity is suboptimal (60–80%) and only a few can distinguish between influenza A and B. Nucleic acid (PCR) techniques still remain less accessible. Complement-fixing and hemagglutination-inhibiting antibodies appear during the second week. Microarrays may be used in the future to monitor the spread of pathogenic viral variants.

Complications

Influenza causes necrosis of the respiratory epithelium, which predisposes to secondary bacterial infections. In turn, bacterial enzymes (eg, proteases, trypsin-like compounds, streptokinase) activate influenza viruses. Frequent complications are acute sinusitis, otitis media, purulent bronchitis, and pneumonia. Children (6–59 months), pregnant women, the elderly (aged 65 years or older), and the chronically ill (including HIV-infected individuals) are at high risk for complications.

Primary viral pneumonia (caused by the influenza virus itself) may occur, particularly in patients with cardiovascular disease and pregnant women and has a high mortality. Secondary bacterial pneumonia due to pneumococci or, less often, staphylococci or *Haemophilus* spp is common. Pericarditis and myocarditis occur infrequently. Rhabdomyolysis is a rare late complication.

Reye syndrome (fatty liver with encephalopathy) is a rare and severe complication of influenza (usually B type) and other viral diseases (eg, varicella), particularly in young children. It consists of rapidly progressive hepatic failure and encephalopathy, and there is a 30% mortality rate. The pathogenesis is unknown, but the syndrome is associated with aspirin use in a variety of viral infections. Hypoglycemia, elevation of serum aminotransferases and blood ammonia, prolonged prothrombin time, and change in mental status all occur within 2–3 weeks after onset of the viral infection. Histologically, the periphery of liver lobules shows striking fatty infiltration and glycogen depletion. Treatment is supportive and directed toward the management of cerebral edema. Other encephalopathic complications of influenza are equally rare and include an acute necrotizing encephalopathy associated with disseminated intravascular coagulation and cytokine storm, with worsening when treated with certain nonsteroidal anti-inflammatory drugs (diclofenac and mefenamic acid), and an acute encephalopathy associated with febrile seizures and the use of theophylline. Influenza infections appear to be an infrequent trigger of Guillain-Barré syndrome.

Prevention

If no contraindication is present, influenza vaccination in October or November each year is recommended for persons over 50 years of age; children (6 months–18 years of age); nursing home residents; patients of any age with chronic medical problems, including lung or heart disease, active malignancy, diabetes, kidney disease, chronic liver disease, immunodeficiencies (such as HIV infection or organ transplant), hemoglobinopathies, or neurologic conditions that impair the clearance of respiratory secretions; pregnant women; and contacts of these high-risk groups, including health care workers, service personnel, and caretakers of children younger than

2 years (see Chapter 30: Common Problems in Infectious Diseases & Antimicrobial Therapy).

The vaccine is contraindicated in persons with well-substantiated hypersensitivity to chicken eggs (based on dietary history) or other components of the vaccine (skin testing can be performed by an allergist), in persons with Guillain–Barré syndrome, or in persons with an acute febrile illness until symptomatic improvement. Concomitant warfarin or corticosteroid therapy is not a contraindication. Side effects are infrequent and include tenderness, redness, or induration at the site for the trivalent inactivated vaccine (intramuscular); and respiratory symptoms for the live attenuated intranasal vaccine.

Chemoprophylaxis can be considered for certain individuals (see Treatment section for definitions) exposed to an infected patient within 2 weeks after vaccination with the trivalent inactivated vaccine; this does not apply for the intranasal live attenuated vaccine since it confers more rapid protection. Chemoprophylaxis may also be considered for those in whom vaccination is contraindicated or not available. Special circumstances that may also warrant consideration of chemoprophylaxis include outbreaks in long-term care facilities, persons living with or in close contact with high risk unvaccinated individuals (eg, health-care providers), persons with immune deficiencies who might not respond to vaccination, unvaccinated staff during response to an outbreak in a closed institutional setting with residents at high risk, and first responders to epidemic situations. Chemoprophylaxis against influenza A and B is traditionally accomplished with the neuraminidase inhibitors oseltamivir (75 mg/d, oral) and zanamivir (10 mg/d, inhaled) but resistance to the former is increasingly prevalent in H1N1 strains. These agents reduce the attack rate among unvaccinated individuals if begun within 48 hours after exposure. In the United States, the M2 inhibitors amantadine and rimantadine are effective against current human H1N1 strains but not the epidemic H1N1 virus of swine origin (see below). In addition, these drugs are not active against other circulating influenza A viruses (H3N2) or B viruses and hence, their use as first-line agents is limited. Occasionally, chemoprophylaxis may need to be continued for the duration of influenza activity in the community, but cost, compliance, and potential adverse effects should be considered as well.

Treatment

Many patients with influenza prefer to rest in bed. Analgesics and a cough mixture may be used. Treatment should be considered for those with a suggestive clinical presentation or with laboratory confirmed influenza and at high risk for developing complications (nursing home residents; patients with chronic pulmonary, cardiovascular, kidney, or liver disease; those with diabetes, active malignancy, immunosuppression, or impairment for managing respiratory secretions), or living with persons at significant risk for them. Maximum benefit is expected with the earliest initiation of therapy. Although the benefit of antiviral therapy after 48 hours of illness is unproven, it should be considered if the patient is hospitalized.

The neuraminidase inhibitors, either inhaled zanamivir (two 5-mg inhalations twice daily for 5 days) or oral oseltamivir (75 mg twice daily for 5 days), are equally effective in the treatment of susceptible strains of influenza. Clinical trials have shown a reduction in the duration of symptoms as well as secondary complications such as otitis, sinusitis, or pneumonia, but not in the rate of hospitalizations or mortality when using these agents. These drugs, when administered early, are effective mainly in high-risk patients over age 12 years. Resistance to neuraminidase inhibitors can occur with prolonged use in immunocompromised patients or in avian (H5N1)-infected patients. High rates (greater than 25%) of oseltamivir resistance in influenza A viruses are reported in surveillance data from several areas of Europe and Africa. In the United States, unfortunately, resistance to oseltamivir is also progressively becoming more prevalent, especially among influenza A (H3N2) strains.

No comprehensive data on global emergence of resistance to zanamivir are available. Both oseltamivir and zanamivir appear less effective in treating influenza B than influenza A viruses. Zanamivir is relatively contraindicated among persons with asthma because of the risk of bronchospasm. Transient neuropsychiatric events, occasionally resulting in self-injury and death, have been reported postmarketing for both neuraminidase inhibitors. Patients receiving these drugs should be closely monitored for any unusual behavior, and healthcare professionals should be notified immediately if such signs occur. Ribavirin (unlabeled usage, 1.1 g/d, diluted to 20 mg/mL, delivered as particulate aerosol with oxygen over 12–18 hours a day for 3–7 days [see Table 32–1]) may be effective in severely ill patients with influenza A or B. Amantadine and rimantadine are inactive against influenza A (H3N2) and influenza B, but they can be used for treatment in the United States, in conjunction with neuraminidase inhibitors, when human-origin influenza A (H1N1) is the predominant viral strain in the community.

Antibacterial antibiotics should be reserved for treatment of bacterial complications. Acetaminophen rather than aspirin should be used for fever in children.

Prognosis

The duration of the uncomplicated illness is 1–7 days, and the prognosis is excellent in healthy, nonelderly adults. Purulent bronchitis and bronchiectasis may result in chronic pulmonary disease and fibrosis that persist throughout life. Most fatalities are due to bacterial pneumonia although exacerbations of other diseases processes, in particular cardiac diseases, occur which contributed to the overall increase in fatalities. Influenza pneumonia has a high mortality rate among pregnant women and persons with a history of rheumatic heart disease. In recent epidemics, the mortality rate has been low except in debilitated individuals.

If the fever persists for more than 4 days with productive cough and white cell count over 10,000/mcL, secondary bacterial infection should be suspected. Pneumococcal pneumonia is the most common such infection, and staphylococcal pneumonia is the most serious.

When to Admit

- Limited availability of supporting services.
- Pneumonia.
- Changes in mental status.

Avian Influenza (H5N1)

Essentials of Diagnosis

- Cases to date in humans, mostly from Southeast Asia.
- Clinically indistinguishable from influenza.
- Epidemiologic factors assist in diagnosis.
- Rapid antigen assays are the means of confirming diagnosis.

General Considerations

The normal hosts for avian influenza viruses are aquatic waterfowl. Although avian influenza was first recognized in Italy in 1878, the current outbreak of highly pathogenic influenza A subtype (H5N1) in poultry was recognized in 1997 in Hong Kong and was followed by the first documented human cases. A massive slaughter of poultry was attempted to contain the disease. New outbreaks of H5N1 influenza in poultry emerged, however, in 2003 and now involve more than 65 countries of East and Southeast Asia, Eurasia, Western and Eastern Europe, and Northern Africa. The 387 confirmed human cases as of January 2009 include 245 deaths (from Azerbaijan, Bangladesh, Cambodia, China, Djibouti, Egypt, Indonesia, Iraq, Lao PDR, Myanmar, Nigeria, Pakistan, Thailand, Turkey, and Vietnam).

Although highly contagious among birds, the transmission of this H5N1 strain from human to human is relatively inefficient and not sustained. The result is only rare cases of person-to-person infection. Occasional transmission to other mammals, including domestic cats and dogs, is also documented.

Most human cases occur after exposure to infected poultry or surfaces contaminated with poultry droppings. Because infection in humans is associated with a mortality rate greater than 50% (over 80% [91 of 113] for Indonesian cases) and the avian H5N1 subtype continues to spread among birds (with many parts of Southeast Asia now considered endemic for the virus), there is worldwide concern that the virus may undergo genetic reassortment or mutation (as with the 1918 strain) and develop greater human-human transmissibility with the potential to produce a global pandemic.

Clinical Findings

Symptoms and Signs

Distinguishing avian influenza from regular influenza is difficult. History of exposure to dead or ill poultry in the prior 10 days, recent travel to Southeast Asia, or contact with known cases should be investigated. The symptoms and signs include predominantly respiratory symptoms (cough and dyspnea), but a variety of other systems may be involved, producing headaches and gastrointestinal complaints in particular. Subclinical disease is relatively rare. With high levels of cytokines being responsible for much of the pathology, prolonged febrile states and generalized malaise are common. Children are preferentially impacted. Most patients die of respiratory failure.

Laboratory Findings

Current commercial rapid antigen tests are not optimally sensitive or specific for detection of H5N1 influenza but are still first-line diagnostic tests because of their widespread availability. Diagnostic yield can be improved by earlier collection of samples. More sensitive RT-PCR assays are usually available through state health departments. An initial negative result in the right clinical setting warrants retesting. Throat or lower respiratory swabs may provide higher yield of detection than nasal swabs. When highly pathogenic strains (eg, H5N1) are suspected, extreme care in the handling of these samples must be observed during preliminary testing. Positive samples must then be forwarded to the appropriate public health authorities for further investigations (eg, culture) in laboratories with the adequate level of biosafety (level 3).

Treatment

Resistance of asian H5N1 influenza strains to amantadine and rimantadine is present in most geographic areas where the virus is found. Reacquisition of sensitivity to these drugs through genetic reassortment is possible. The current first-line recommendation is to use the neuraminidase inhibitor oseltamivir, 75 mg twice daily for 5 days administered within 48 hours from onset of illness. A higher dose (150 mg twice daily), longer duration, and possible combination therapy with amantadine or rimantadine (in countries where A (H5N1) viruses are likely to be susceptible to adamantanes) may be considered in those patients with pneumonia or progressive disease. Recent evidence of resistance to oseltamivir is reported. Although inhaled zanamivir has proven effective in treating seasonal influenza, no data of its efficacy against H5N1 strains are available. Therapy should still be considered for patients with severe avian influenza disease even after several days of onset. Postexposure prophylaxis with 75 mg of oseltamivir once daily for 7–10 days should be given to household contacts of documented cases. Personnel exposed to those patients should be monitored for symptoms. Careful surveillance of new human cases and prudent stockpiling of medications with establishment of an infrastructure for dissemination are essential modalities of control. Nonpharmacologic means of control include masks; social distancing; quarantine; travel limitations; and infrastructure development, particularly for emergency departments.

One human vaccine against H5N1 influenza is licensed but not yet marketed in the United States. This vaccine does not contain adjuvant and as a result, its immunogenicity is only modest. A vaccine with oil-in-water emulsion-based adjuvant is available in Europe. Several other vaccine candidates are undergoing clinical trials. Conventional tricomponent inactivated influenza vaccines provide only partial protection.

Prevention of exposure to avian influenza strains also includes hygienic practices during handling of poultry products, including handwashing and prevention of cross-contamination, as well as thorough cooking of poultry products (to 70 °C). Nonetheless, the risk of acquiring avian influenza through the consumption of poultry products is still very small.

Swine-origin Influenza (H1N1/A/California/04/2009)

Essentials of Diagnosis

- Influenza-like illness with consistent epidemiologic background.
- Respiratory swab allows local screen and more specific analysis by state public health laboratories.

General Considerations

Because the human influenza virus of avian, human, and swine sources can grow readily in the respiratory tract of pigs, they are considered a "mixing vessel" for gene reassortment between strains. A current outbreak of pandemic swine-origin (H1N1) influenza virus (S-OIV) emerged in Mexico City in March 2009. In the United States, the first cases occurred in metropolitan San Diego and San Antonio, and the outbreak rapidly spread throughout the United States. As of June 1, 2009, cases were also reported from over 40 nations among the five continents. Although referred in the popular press to as "swine flu," this infection is caused by a new influenza A strain that is a reassortment of swine, avian, and human influenza strains (eg, triple-reassortant); thus, "swine flu" is a misnomer. The WHO guidelines suggest that influenza viruses be named after their viral type (A, B, or C), host (if non-human), place of isolation, isolation number, and year of isolation (separated by slashes).

Hence, a more appropriate term to identify this virus is influenza A/California/04/2009, but its utility might be restricted to physicians and scientists.

Clinical Findings

Symptoms and Signs

This current strain of S-OIV appears to cause typical influenza symptoms (fever, malaise, myalgias, cough, sore throat, rhinorrhea, shortness of breath) commonly accompanied by gastrointestinal manifestations (especially diarrhea). The disease has an incubation period of 2–9 days and preferentially impacts young adults. This age specificity might reflect previous exposure with related strains in people over the age of 40 years (conferring some degree of cross-protection) but also to some case-ascertainment bias due to more young people being tested as part of outbreaks in schools or the workplace. The infectivity of the new strain appears to be unusually high. Most patients report a relatively mild illness with full recovery. While a number of deaths were reported from early cases in metropolitan Mexico City, S-OIV seems less likely to cause death than other pandemic viruses (ie, 1918 pandemic virus). The mortality rate of S-OIV seems to be similar to seasonal influenza (mortality rate < 0.5%); however, this could change as the pandemic evolves.

Laboratory Findings

A respiratory swab for novel S-OIV testing should be taken and placed in a refrigerator (not a freezer). State public health laboratories can then perform a PCR and subtype testing on identified samples. For current case definitions and guidelines on specimen collecting and processing and for confirmation testing, see www.cdc.gov/h1n1flu/ or contact the local public health department. While waiting for confirmatory results, local laboratories can perform rapid immunofluorescence or enzyme immunoassays that can differentiate between influenza viruses types A and B, but their results should be interpreted with caution due to their limited sensitivity (typically about 60%) and inability to differentiate between human- and swine-origin viruses.

Treatment

Treatment entails using neuraminidase inhibitors (oseltamivir or zanamivir) at standard dosages. The virus is usually resistant to the adamantanes (amantadine or rimantadine). Please see the regular influenza section for side effects and concerns with these medications. At the time of this review, the recommendations on which patients should receive specific antiviral therapy for S-OIV infections are similar to those for seasonal influenza. As additional information becomes available, however, specific recommendations may change. Updated advice can be found at http://www.cdc.gov/h1n1flu/recommendations.htm.

Prevention

A polyvalent vaccine is under development, and this vaccine may require that patients at risk take the vaccine (which may be two dosages) plus the standard vaccine (for a total of three dosages). In general, persons with S-OIV infection should be considered potentially infectious from 1 day before to 7 days following illness onset. Children, especially younger ones, may be infectious up to 10 days. Any hospital patient in whom the infection is suspected should be isolated in individual rooms with standard and contact precautions plus eye protection. Strict adherence to hand hygiene with soap and water or an alcohol-based hand sanitizer and immediate removal of gloves and other equipment after contact with respiratory secretions is essential. For procedures likely to generate aerosols (eg, bronchoscopy, elective intubation, suctioning, administering nebulized medications), an airborne infection isolation room (AIIR) can be used, with air exhausted directly outside or recirculated after filtration by a high efficiency particulate air (HEPA) filter. The patient should wear surgical masks to contain secretions when outside a patient room, and healthcare personnel in contact with patients should wear a fit-tested disposable N95 respirator or equivalent (eg, powered air purifying respirator). This latter recommendation differs from that for cases of seasonal influenza because of the undetermined potential transmissibility of this new reassortment virus. Precautions should be maintained until 7 days from symptom onset or until the resolution of symptoms, whichever is longer. Postexposure prophylaxis should be considered for close contacts of patients (confirmed, probable, or suspected) who are at high risk for complications of influenza (see section on seasonal influenza) as well as for healthcare personnel, public health workers, or first responders who have had a recognized, unprotected close contact exposure to a person with novel (H1N1) influenza virus infection (confirmed, probable, or suspected) during that person's infectious period. Despite limited data of the safety of neuraminidase inhibitors, the CDC recommends considering postexposure prophylaxis as well in this population. Healthcare professionals should frequently refer to the CDC guidelines for changes in these recommendations (http://www.cdc.gov/h1n1flu/recommendations.htm). There are no currently documented or substantiated indications for travel restrictions, culling of animals, or widespread school closures. There is concern that in heavily impacted, dense urban areas (major cities of Asia or Africa, for example) the number of cases may significantly increase in the winter of 2009–2010. Concerned professionals should refer to MMWR or

the CDC (www.cdc.gov/h1n1flu/) and WHO websites (http://www.who.int/csr/disease/swineflu/en/) for evolving updates about this pandemic.

Severe Acute Respiratory Syndrome (SARS)

Essentials of Diagnosis

- Mild, moderate, or severe respiratory illness.
- Travel to endemic area within 10 days before symptom onset, including mainland China, Hong Kong, Singapore, Taiwan, Vietnam, and Toronto.

- Persistent fever; dry cough, dyspnea in most.
- Diagnosis confirmed by antibody testing or isolation of virus.
- No specific treatment; mortality as high as 10% in clinically diagnosed cases.

General Considerations

SARS is a respiratory syndrome of varying severity but capable of causing death in as many as 10% of clinically established cases. It is caused by an apparently unique coronavirus. The earliest cases were traced to a health care worker in Guangdong Province in China in late 2002, with rapid spread thereafter to Hong Kong, Singapore, Vietnam, Taiwan, and Toronto. The primary mode of transmission appears to be through direct or indirect contact of mucous membranes (eyes, nose, or mouth) with infectious respiratory droplets or fomites. Epidemiologic data also suggest airborne spread. The use of aerosol-generating procedures (endotracheal intubation, bronchoscopy, nebulization treatments) in hospitals may amplify the transmission of the SARS coronavirus. The virus is shed in stools but the role of fecal–oral transmission is unknown. The natural reservoir appears to be the horseshoe bat (which eats and drops fruits ingested by civets, the earlier presumed reservoir and a likely amplifying host).

The variable distribution of cases throughout Asia and

Canada is considered a consequence of spread through travel. The virus is sufficiently virulent that it may be transmitted and acquired by patients during brief stops in airports. As a result, sporadic confirmed and suspected cases have appeared throughout the United States. The 2003 outbreak involved 8096 probable cases in about 28 countries, with 774 fatalities. In 2004, nine cases associated with laboratory and subsequent secondary exposure were reported from Beijing, China. No new cases have been reported since then.

Clinical Findings

Symptoms and Signs

SARS is considered an atypical pneumonia that affects persons in all age groups. The CDC recognizes asymptomatic or mild cases, moderate disease, and severe respiratory illness. The incubation period is 2–7 days, and it can be spread to contacts of affected patients for 10 days. The mean time from onset of clinical symptoms to hospital admission is 3–5 days. In all clinical cases, persistent fever is present; chills or rigor (or both), cough, shortness of breath, rales, and rhonchi are the rule. Many patients report headache, myalgias, and sore throat as well. A watery diarrhea occurs in some patients during the course of the illness. Elderly patients may report malaise and delirium, without the typical febrile response. No single symptom or sign is diagnostic or highly suggestive, and the history and physical examination of a patient in whom SARS in suspected are to be interpreted in this context.

Laboratory Findings and Imaging

Leukopenia and especially lymphopenia are observed commonly. A low-grade disseminated intravascular coagulation (thrombocytopenia, prolonged activated thromboplastin time, and elevated D-dimer level) is present in many patients. Other abnormalities include modest elevations of ALT and creatine kinase. Arterial oxygen saturation is less than 95% in 80% of affected individuals, and pulmonary infiltrates are noted in all. The roentgenographic pattern is not specific, and severe cases may progress to ARDS, with extensive bilateral consolidation. A high-resolution CT scan is abnormal (ground-glass opacifications or focal consolidation) in 67% of patients with initially normal chest radiographs. Serum serologies, including enzyme immunoassays and fluorescent antibody assays, are available through public health departments at the state level, although seroconversion may not occur until 3 weeks after the onset of symptoms.

The detection rates for the virus using conventional RT-PCR are generally low in the first week of illness. Urine, nasopharyngeal aspirate, and stool specimens are positive in 42%, 68%, and 97%, respectively, on day 14 of illness.

Although viral isolation is possible, it is a technically laborious and time-consuming procedure.

Complications

As with any viral pneumonia, pulmonary decompensation is the most feared problem. ARDS occurs in about 16% patients, and about 20–30% of patients require intubation and mechanical ventilation. Sequelae of intensive care include infection with nosocomial pathogens, tension pneumothorax from ventilation at high peak pressures, and noncardiogenic pulmonary edema.

Prevention

Health care workers engaged in procedures that involve activities such as intubation, suctioning, and nebulization are at high risk for acquiring the virus. Transmission may occur shortly after the development of symptoms and perhaps before the appearance of fever, cough, and dyspnea. Thus, an increased level of suspicion is critical, and isolation of high-risk patients is essential. Simple hygienic measures (such as handwashing after touching patients, use of appropriate and well-fitted face masks, and early introduction of infection control measures, including quarantine) may help reduce transmission.

Measures enacted for air travelers have included screening for fever and compatible symptoms and quarantining in the home for high-risk exposed persons.

Continual reporting of suspected cases is crucial, as is awareness of restrictions on international travel. The most cautious modalities include monitoring for 10 days after the last potential exposure and confinement of recovering patients for a similar interval. The efficacy of facemasks is established for preventing hospital-acquired infections, although the validity for their usage in the community remains unsubstantiated.

Treatment

Severe cases require intensive support. Although a number of different agents including ribavirin (400–600 mg/d and 4 g/d), lopinavir/ritonavir (400 mg/100 mg), interferon type I, intravenous immunoglobulin, and systemic corticosteroids were used to treat SARS patients during the 2003 epidemic, the treatment efficacy of these therapeutic agents remains inconclusive and further research is needed. Subsequent studies with ribavirin show no activity against the virus in vitro, and a retrospective analysis of the epidemic in Toronto suggests worse outcomes in patients who receive the drug.

Prognosis

The overall mortality rate of identified cases is about 14%. Mortality is age-related, ranging from less than 1% in persons under 24 years of age to greater than 50% in persons over 65 years of age. Poor prognostic factors include advanced age, chronic hepatitis B infection treated with lamivudine, high initial or high peak lactate dehydrogenase concentration, high neutrophil count on presentation, diabetes mellitus, acute kidney disease, and low counts of CD4 and CD8 on presentation. Many subclinical cases probably go undiagnosed. Seasonality, as with influenza, is not established.

Adenovirus Infections

Adenoviruses (there are over at least 52 serotypes) produce a variety of clinical syndromes. These infections are usually self-limited or clinically inapparent and most common among infants, young children, and military recruits. Adenoviruses, however, may cause significant morbidity and mortality in immunocompromised persons, such as HIV-infected persons and liver, kidney, and lung and hematopoietic stem cell transplant, cancer chemotherapy, and COPD patients. The incubation period is 4–9 days. Adenoviruses, although a common cause of human disease, also receive particular recognition through their role as vectors in gene therapy.

Clinical syndromes of adenovirus infection, often overlapping, include the following. The common cold (see Chapter 8: Ear, Nose, & Throat Disorders) is characterized by rhinitis, pharyngitis, and mild malaise without fever. Nonstreptococcal exudative pharyngitis is characterized by fever lasting 2–12 days and accompanied by malaise and myalgia. Conjunctivitis is often present. Lower respiratory tract infection may occur, including bronchiolitis, suggested by cough and râles, or pneumonia (types 3, 4, and 7 commonly cause acute respiratory disease and pneumonia). Adenovirus type 14 is increasingly reported as a cause of severe and sometimes fatal pneumonia in those with chronic lung disease, but it is also seen in healthy young adults. Pharyngoconjunctival fever is manifested by fever and malaise, conjunctivitis (often unilateral), mild pharyngitis, and cervical adenitis. Epidemic keratoconjunctivitis (transmissible person to person) occurs in adults and is manifested by bilateral conjunctival redness, pain, tearing, and an enlarged preauricular lymph node (multiple types may be involved in a single outbreak). Keratitis may lead to subepithelial opacities (especially with types 8, 19, or 37). Acute hemorrhagic cystitis is a disorder of children often associated with adenovirus type 11 and 21. Sexually transmitted genitourinary ulcers and urethritis may be caused by types 2, 8, and 37 in particular. Adenoviruses also cause acute gastroenteritis (types 40 and 41), mesenteric adenitis, acute appendicitis, and intussusception. Rarely, they are associated with encephalitis, acute flaccid paralysis, and pericarditis. Adenovirus is commonly identified in endomyocardial tissue of patients with myocarditis and dilated cardiomyopathy. Risk factors associated with severity of infection include youth, chronic underlying infections, recent transplantation, and serotypes 5 or 21.

Hepatitis (type 5 adenovirus), pneumonia, and hemorrhagic cystitis (types 11 and 34) tend to develop in infected liver, lung, or kidney transplant recipients, respectively. Syndromes that may develop in hematopoietic stem cell transplant patients, include hepatitis, pneumonia, hemorrhagic cystitis, tubulointerstitial nephritis, colitis, and encephalitis.

A rapid diagnostic direct fluorescence assay or enzyme immunoassay may assist with diagnosis and a quantitative real-time rapid-cycle PCR is useful in distinguishing disease from colonization, especially in hematologic cell transplant patients. Viral culture remains the gold standard, but cultures delay the diagnosis.

Treatment is symptomatic. Ribavirin and cidofovir are used in immunocompromised individuals with occasional success, although the latter is attendant with significant renal toxicity, in immunocompromised persons among whom reduced immunosuppression is indicated. Adoptive immunotherapy with transfusion of adenovirus-specific T cells is currently being investigated. Typing of isolates is useful epidemiologically and in distinguishing transmission from endogenous reactivation. Complications of adenovirus pneumonia in children include bronchiolitis obliterans.

Vaccines are not available for general use. Live oral vaccines containing attenuated type 4 and type 7 were used in military personnel, but they have been discontinued.

serotype 14: a new respiratory threat? Clin Infect Dis. 2008 Feb 1;46(3):421–5. [PMID: 18173356]

Parvovirus Infections

Parvovirus B19 infects human erythroid precursor cells. It is quite widespread (by age 15 years about 50% of children have detectable IgG) and its transmission occurs through respiratory secretions and saliva, through the placenta (vertical transmission), and through administration of blood products. The incubation period is 4–14 days. Chronic forms of the infection can occur. **Bocavirus,** another parvovirus, was recently uncovered as a cause of winter acute respiratory disease in children and adults.

Clinical Findings

Symptoms and Signs

Parvovirus B19 causes several syndromes (see micrograph) and manifests differently in various populations.

Fig.
Parvovirus infection. (Peripheral blood, 50 x.) A giant pronormoblast is shown in the middle of the field. This is

a very unusual finding in peripheral blood and represents an early erythroid cell that has been transformed by infection with parvovirus B19. Whereas in normal individuals parvovirus infection can cause suppression of hematopoiesis that is of very little consequence, it can also cause severe life-threatening anemia in patients with chronic hemolytic states. (Courtesy of L Damon.)

Children

In children, an exanthematous illness ("fifth disease," erythema infectiosum) is characterized by a fiery red "slapped cheek" appearance, circumoral pallor, and a subsequent lacy, maculopapular, evanescent rash on the trunk and limbs. Malaise, headache, and pruritus (especially on the palms and soles) occur. Systemic symptoms and fever are mostly abated by the time of rash appearance.

Immuncompromised patients

In immunosuppressed patients, including those with HIV infection or transplanted organs, or with hematologic conditions such as sickle cell disease, transient aplastic crisis and pure red blood cell aplasia may occur. Bone marrow aspirates reveal absence of mature erythroid precursors and characteristic giant pronormoblasts.

Adults

A limited nonerosive symmetric polyarthritis that mimics lupus erythematosus and rheumatoid arthritis, preferentially involving the metacarpophalangeal joints of the hands and the wrists and knees, can develop in middle-aged persons (especially women) but can also occur in children. Rashes, especially facial, are less common in adults.

Rare reported presentations include myocarditis with infarction, constrictive pericarditis, hepatitis, pneumonitis, neutropenia, thrombocytopenia, a lupus-like syndrome, glomerulopathy, CNS vasculitis, and a chronic fatigue syndrome. Subclinical infection is documented among patients with sickle cell disease.

In pregnancy, fetal loss and hydrops fetalis are reported sequelae. Pregnant women with a recent exposure or with suggestive symptoms should be tested for the disease and carefully monitored if results are positive.

Laboratory Findings

The diagnosis is clinical (Table 32–2) but may be confirmed by an elevated titer of IgM anti-parvovirus antibodies in serum or with PCR in serum or bone marrow. Autoimmune antibodies (antiphospholipid and antineutrophil cytoplasmic antibodies) can be present and are thought to be a consequence of molecular mimicry.

Complications

Uncommon complications include encephalitis, chronic hemolytic anemia, thrombotic thrombocytopenic purpuric syndrome, acute postinfectious glomerulonephritis, and hepatitis.

Treatment

Treatment in healthy persons is symptomatic (nonsteroidal anti-inflammatory drugs are used to treat arthralgias, and transfusions are used to treat transient aplastic crises). In immunosuppressed patients, intravenous immunoglobulin can aid in the reduction of anemia. Intrauterine blood transfusion can be considered in severe fetal anemia.

Prevention & Prognosis

Screening of donated blood could potentially prevent transfusion-related infection. Several nosocomial outbreaks have been documented. In these cases, standard containment guidelines, including handwashing after patient exposure and avoiding contact with pregnant women are paramount.

The prognosis is generally excellent in immunocompetent individuals. In immunosuppressed patients, persistent anemia may require prolonged transfusion dependence. Remission of parvovirus infection in AIDS patients may occur with HAART, though the immune restoration syndrome is also reported.

Poxvirus Infections

Among the nine poxviruses causing disease in humans, the following are clinically important.

1. **Variola/vaccinia:** Smallpox (variola) was a highly contagious disease associated with high mortality and disabling sequelae. Its manifestations included severe headache, acute onset of fever, prostration and a rash characterized by the uniform progression from macules to papules to firm, deep seated vesicles or pustules. The synchronous progression in smallpox readily differentiates lesions from those of varicella (see also Chapter 6: Dermatologic Disorders).

Complications of smallpox included bacterial superinfections (cellulitis and pneumonia), encephalitis, and keratitis with corneal ulcerations a risk factor for blindness. Effective vaccination led to its global elimination by 1979 and routine vaccination stopped in 1985. Despite the recommendation of destroying remaining samples of this virus, significant concern exists for the potential misuse of these repositories in military or terrorist activities. Smallpox should be considered, in concordance with the CDC's Smallpox Response Plan (www.bt.cdc.gov/agent/smallpox/response-plan/index.asp), in any patient with fever and a characteristic rash (see above) for which other etiologies such as herpes infections, drug reactions, erythema multiforme or other infections are unlikely. Such patients should be placed in airborne and contact isolation and the official agency contacted (CDC Emergency Preparedness and Response Branch; 770-488-7100). The Department of Defense and the US Department of Health and Human Services (DHHS) launched military and civilian vaccination programs by January 2003.

The presence of any of the following in the person being vaccinated or in his or her household contacts is a contraindication to vaccination: any form of immunosuppression, eczema or other forms of dermatitis (active or in remission), or allergy to any component of the vaccine. Infants younger than 1 year and pregnant or breastfeeding women should not receive the vaccine.

Adverse reactions to the vaccine include generalized vaccinia; eczema vaccinatum, which is a more serious local or disseminated vesicular rash in patients with preexisting eczema or atopic dermatitis; and progressive vaccinia occurring in immunocompromised persons associated with significant widespread necrosis and a high mortality even after administration of vaccinia immune globulin (VIG). Other adverse reactions are generalized symptoms (fatigue, headache, muscle aches, and fever, referred as the **acute vaccinia syndrome**), myocarditis, pericarditis, unexpected ischemic cardiac events, postvaccinial encephalitis, and erythema multiforme major. The occurrence of vaccinia-related disease is also described in contacts of vaccinees, including rare cases of sexually transmitted disease. Inoculation of the vaccine in inappropriate sites (eg, eyes) is unfortunately common. Asymptomatic vaccinia viremia can be detected up to 21 days post vaccination and no blood donation should occur during this interval. Cidofovir shows activity against poxviruses and can be considered for treatment of these poxviral conditions.

2. **Molluscum contagiosum** may be transmitted sexually or by other close contact. It is manifested by pearly, raised, umbilicated skin nodules sparing the palms and soles. Keratoconjunctivitis can occur. Marked and persistent lesions in AIDS patients respond readily to combination antiretroviral therapy. Curettage is most effective for limited lesions. Reportedly effective forms of therapy include catharidin (blisters are a side effect), cimetidine and CO_2 laser therapy combined with natural interferon- gel, salicylic and glycolic acids, and imiquimod cream (5%). Multiple courses of therapy are

often needed.

3. **Orf** (contagious pustular dermatitis, or ecthyma contagiosa) and **paravaccinia** (milker's nodules) are occupational diseases acquired by contact with sheep and cattle, respectively (see photograph). Orf also occurs among children with ruminant exposures. Orf anecdotally responds to imiquimod.

Fig.

Orf skin ulcer. A painful finger ulcer (panel A) developed in a 58-year-old man who was also found to have a palpable olecranal lymph node. The rest of his examination was unremarkable. A biopsy specimen of the lesion, fixed and sectioned thinly for transmission electron microscopy, revealed numbers of parapoxvirus particles. At a low magnification, extreme swelling of infected cells can be seen, resulting in degeneration (panel B, 6000 x). Higher magnification of a section of panel B (see box) clearly shows characteristic oval virions consisting of a core (c) surrounded by an envelope (e) (panel C, x 60,000). When questioned about risk factors for parapoxvirus infection, the patient reported contacts with sheep in a slaughterhouse. The parapoxvirus particles identified were presumed to be orf viruses, which cause a common skin disease of sheep and goats that is occasionally transmitted to humans. All rights reserved.

4. **Monkeypox**, first identified in 1970, is enzootic in the rain forests of equatorial Africa and presents in humans as a syndrome similar to smallpox. The incubation period is about 12 days, and limited person-to-person spread occurs. African mortality rates vary from 3% to 11% depending on the immune status of the patient. Secondary attack rates appear to be about 10%. The first community-acquired outbreak in the United States of monkeypox occurred in 2003 in Wisconsin and other states of the upper Midwest. The source appeared to be imported Gambian giant rats via consequent exposure of prairie dogs. Other susceptible animals include nonhuman primates, rabbits, and rodents. Confusion with smallpox and varicella occurs; however, lymphadenopathy is a prominent feature of monkeypox infection (seen in up to 90% of unvaccinated persons), and skin lesions of the palms and soles, frequently seen in these poxviruses, are uncommon in varicella infection. Suspected cases should

be placed on standard, contact and droplet precautions; and local and state public health officials, and the CDC should be notified for assistance with the confirmation of the diagnosis (electron microscopy, viral culture, ELISA, PCR). Cidofovir is effective against monkeypox, and IVIG can be used in selected cases.

Other general precautions that should be taken are avoidance of contact with prairie dogs and Gambian giant rats (whose illness is manifested by alopecia, rash, and ocular or nasal discharge), appropriate care and isolation of those exposed within 3 prior weeks to such animals, and veterinary examination and investigation of suspect animals through health departments. Vaccinia immunization is effective against monkeypox and is recommended, if no contraindication exists (outlined above), for those involved in the investigation of the outbreak and for healthcare workers caring for those infected with monkeypox. Post exposure vaccination is also advised for documented contacts of infected persons or animals. US federal agencies currently prohibit the importation of African rodents.

Viruses & Gastroenteritis

Viruses are responsible for at least 30–40% of cases of infectious diarrhea in the United States. These agents include rotaviruses; caliciviruses, including noroviruses such as Norwalk virus; astroviruses; enteric adenoviruses; and, less often, toroviruses, coronaviruses, picornaviruses, and pestiviruses.

Rotaviruses are the leading worldwide cause of dehydrating gastroenteritis in young children and are associated with significant morbidity and mortality (nearly 600,000 persons die each year in developing countries). Children aged 6 months to 2 years are the most affected. By age 5, virtually every child has been infected with this pathogen. There are **seven groups of rotaviruses** (A-G), but group A strains cause the vast majority of these infections while group B and C strains are limited to outbreaks in more restricted settings.

Rotavirus infections follow an endemic pattern, especially in the tropics, although they peak during the winter in temperate regions. The virus is transmitted by fecal-oral route and can be shed in feces for up to 3 weeks in severe infections. In outbreak settings (eg, daycare centers), the virus is ubiquitously found in the environment, and secondary attack rates are between 16% and 30% (including household contacts). The disease is usually mild and self-limiting. A 2- to 3-day prodrome of fever and vomiting is followed by nonbloody diarrhea (up to 10–20 bowel movements per day) lasting for 1–4 days. The method of choice for diagnosis is PCR of the stool. Treatment is symptomatic, with fluid and electrolyte replacement. Local intestinal immunity gives protection against successive infection. Two oral rotavirus vaccines are available in the United States: pentavalent human-bovine reassortment rotavirus vaccine (PRV, RotaTeq; to be given at 2, 4, and 6 months of age) and attenuated human rotavirus vaccine (HRV, Rotarix; to be given at 2 and 4 months of age). Contraindications include allergy to any of the vaccine ingredients, previous allergic reaction to the vaccine, and immunodeficiency.

Noroviruses, such as **Norwalk virus,** are the major cause of epidemic gastroenteritis. They appear to evolve by antigenic drift (similar to influenza). While 90% of young adults show serologic evidence of past infection, no long-lasting protective immunity develops and reinfections are common. In the United States, noroviruses are responsible for over 90% of reported nonbacterial gastroenteritis outbreaks during cold weather intervals (hence the colloquial name "gastric flu"). Outbreak environments include restaurants, long-term care facilities, hospitals, schools, daycare centers, vacation destinations (including cruise ships), and Middle Eastern military bases deployed abroad. Although transmission is usually fecal–oral, airborne and waterborne transmission are also documented. A short incubation period (24–48 hours), a short symptomatic illness (12–60 hours), a high frequency (> 50%) of vomiting, and absence of bacterial pathogens in stool samples are highly predictive of norovirus gastroenteritis. RT-PCR of stool samples is used for epidemiologic purposes. Treatment is largely symptomatic.

Outbreak control for both rotavirus and noroviurs infections include strict adherence to general hygienic measures, cohorting of sick patients, contact precautions for symptomatic hospitalized patients, exclusion from work of symptomatic staff until symptom resolution (or 48–72 h after this for norovirus disease), and proper decontamination procedures.

The presence of antibodies is not associated with protection against reinfection.

Coxsackievirus Infections

Coxsackievirus infections cause several clinical syndromes. As with other enteroviruses, infections are most common during the summer. Two groups, A and B, are defined either serologically or by mouse bioassay. There are more than 50 serotypes.

Clinical Findings

Symptoms and Signs

The clinical syndromes associated with coxsackievirus infection may be described briefly as follows.

Summer grippe (A and B)

A febrile illness, principally of children, summer grippe usually lasts 1–4 days. Minor symptoms of upper respiratory tract infection are often present.

Herpangina (A2–6, 10: B3)

Sudden onset of fever, which may be as high as 40.6 °C, sometimes with febrile convulsions; headache, myalgia, and vomiting; and sore throat, characterized early by petechiae or papules on the soft palate that become shallow ulcers in about 3 days and then heal. Treatment is symtomatic.

Epidemic pleurodynia (Bornholm disease) (B1–5)

Pleuritic pain is prominent, and tenderness, hyperesthesia, and muscle swelling are present over the area of diaphragmatic attachment. Other findings include headache, sore throat, malaise, nausea, and fever. Orchitis and aseptic meningitis occur in less than 10% of patients. Most patients are ill for 4–6 days.

Aseptic meningitis (A and B) and other neurologic syndromes

Fever, headache, nausea, vomiting, stiff neck, drowsiness, and cerebrospinal fluid lymphocytosis without chemical abnormalities may occur, and pediatric clusters of group B (especially B5) meningitis are reported. Focal encephalitis and transverse myelitis are reported with coxsackievirus group A. A disseminated encephalitis occurs after group B infection, and acute flaccid paralysis is reported with both coxsackievirus group A and B. Severe neonatal illnesses are reported including encephalomyocarditis.

Acute nonspecific pericarditis (B types)

Sudden onset of anterior chest pain, often worse with inspiration and in the supine position, is typical. Fever, myalgia, headache, and pericardial friction rub appear early and these symptoms are often transient. Evidence for pericardial effusion on imaging studies is often present, and the occasional patient has a paradoxical pulse. Electrocardiographic evidence of pericarditis is often present. Relapses may occur.

Myocarditis (B1–5)

Heart failure in the neonatal period secondary to in utero myocarditis and over 20% of adult cases of myocarditis and dilated cardiomyopathy are associated with group B (especially B3) infections.

Hand, foot, and mouth disease (A5, 10, 16)

This disease is sometimes epidemic and is characterized by stomatitis and a vesicular rash on hands and feet. Enterovirus 71 is also a causative agent.

Epidemic conjunctivitis

As with enterovirus 70 (see below), the A24 variant of coxsackievirus is associated with acute epidemic hemorrhagic conjunctivitis in tropical areas with recent outbreaks in southern China and Pakistan.

Other syndromes associated with coxsackievirus infections

These include rhabdomyolysis, fulminant neonatal hepatitis (occurs rarely), glomerulopathy (group B infections), and type 1 diabetes mellitus (mainly with group B infections), although definitive causality is not established. A pathogenic role in primary Sjögren syndrome and acute myocardial infarction has also been proposed for group B coxsackievirus infections.

Laboratory Findings

Routine laboratory studies show no characteristic abnormalities. Neutralizing antibodies appear during convalescence. The virus may be isolated from throat washings or stools inoculated into suckling mice. Viral culture is expensive, labor demanding, and requires several days for results. A PCR test for enterovirus RNA is available and, although it cannot identify the serotype, it appears to be useful, particularly in cases of meningitis.

Treatment & Prognosis

Treatment is symptomatic. With the exception of meningitis, myocarditis, pericarditis, perhaps diabetes, and rare illnesses such as pancreatitis or polio-like syndrome, the syndromes caused by coxsackieviruses are benign and self-limited. Two controlled trials showed a potential clinical benefit with pleconaril for patients with enteroviral meningitis although the compassionate use of this drug has stopped. There are anecdotal reports of success with intravenous immunoglobulin in severe disease.

Brunetti L et al. Treatment of viral myocarditis caused by coxsackievirus B. Am J Health Syst Pharm. 2008 Jan 15;65(2):132–7. [PMID: 18192257]

Echovirus Infections

Echoviruses are enteroviruses that produce several clinical syndromes, particularly in children. Infection is most common during summer. Among reported specimens, death ensues in about 3%. Males younger than

20 years are more commonly infected than other persons.

Over 30 serotypes have been demonstrated and the most common serotypes for disease are types 6, 9, 11, and 30. Most can cause aseptic meningitis, which may be associated with a rubelliform rash. Types 30 and 13 (the latter also associated with meningitis) outbreaks are increasingly reported globally, including five epidemics of the latter in the United States. Transmission is primarily fecal–oral. Handwashing is an effective control measure in outbreaks of aseptic meningitis. Outbreaks related to fecal contamination of water sources, including drinking water and swimming and bathing pools, were reported in the past.

Besides meningitis, other conditions associated with echoviruses range from common respiratory diseases (bronchiolitis occurs often in children) and epidemic diarrhea to myocarditis, a hemorrhagic obstetric syndrome, keratoconjunctivitis, hepatitis with coagulopathy, leukocytoclastic vasculitis, and neonatal as well as adult cases of encephalitis and sepsis, interstitial pneumonitis, hemophagocytic syndromes (in children with cancer), sudden deafness, encephalitis, optic neuritis, uveitis, and septic shock. Echoviruses, and enteroviruses in general, are also a common cause of nonspecific exanthems.

The role of enteroviruses in the development of type 1 diabetes mellitus and in the chronic fatigue syndrome are under study.

As with other enterovirus infections, diagnosis is best established by correlation of clinical, epidemiologic, and laboratory evidence. Cytopathic effects are produced in tissue culture after recovery of virus from throat washings, blood, or cerebrospinal fluid. An enterovirus PCR of the cerebrospinal fluid can assist in the diagnosis. Fourfold or greater rises in antibody titer signify systemic infection.

Treatment is usually symptomatic, and the prognosis is excellent, though there are reports of mild paralysis after CNS infection. Pleconaril, investigational, appears to be of some use among meningitis patients with more severe disease in shortening the course of illness.

From a public health standpoint, the prevention of fecal–oral contamination and the maintenance of pool hygiene through chlorination and pH control are important.

Jacques J et al. Epidemiological, molecular, and clinical features of enterovirus respiratory infections in French children between 1999 and 2005. J Clin Microbiol. 2008 Jan;46(1):206–13. [PMID: 18003804]

Enteroviruses 70 & 71

Several clinical syndromes are being described in association with newer enteroviruses. **Enterovirus 70,** a ubiquitous agent first identified in 1969 and responsible for abrupt bilateral eye discharge and subconjunctival hemorrhage with occasional systemic symptoms, is most commonly associated with **acute hemorrhagic conjunctivitis. Enterovirus 71** is associated with **hand, foot, and mouth disease** (HFMD) as well as a form of **epidemic encephalitis** associated on occasion with pulmonary edema, and **acute flaccid paralysis**. Because of lower herd immunity, HFMD tends to infect the very young (under age 5) in nonendemic areas. Disease is usually more severe and sequelae more common than with other enteroviruses. The sequelae include central hypoventilation, dysphagia, and limb weakness. An outbreak of enterovirus 71 infections occurred in Colorado between 2003 and 2005.

Diagnosis of both entities is facilitated by the clinical and epidemiologic findings with the isolation of the suspect agent from conjunctival scraping for enterovirus 70 or vesicle swabs, body secretions, or cerebrospinal fluid for enterovirus 71. An IgM capture ELISA is being developed for the latter agent.

Treatment of both entities remains largely symptomatic, though pleconaril (see above) may be of some use. The major complication associated with enterovirus 70 is the rare development of an acute neurologic illness with motor paralysis akin to poliomyelitis. Attention-deficit with hyperactivity occurs in about 20% with confirmed infection.

Household contacts, especially children under 6 months of age, are at particular risk for enterovirus 71 acquisition. A commercial disinfectant, Virkon S, at 1–2% application, appears to reduce infectivity titers. A stage-based supportive treatment for enterovirus 71 infections, recognizing the potential for late onset CNS disease and cardiopulmonary failure is important.

Enterovirus 72 is another term for hepatitis A virus (see Chapter 16: Liver, Biliary Tract, & Pancreas Disorders).

Gau SS et al. Attention-deficit/hyperactivity-related symptoms among children with enterovirus 71 infection of the central nervous system. Pediatrics. 2008 Aug;122(2):e452–8. [PMID: 18606624]

Qiu J. Enterovirus 71 infection: a new threat to global public health? Lancet Neurol. 2008 Oct;7(10):868–9. [PMID: 18848307]

Human Parechovirus Infection

Four types of parechovirus (a picornavirus first recognized in 2000) were recognized by 2007. They are responsible for otitis, respiratory, and gastrointestinal illness in young children; neonatal sepsis; flaccid paralysis; and cerebral infections, including aseptic meningitis and encephalitis. Severe disease is most often found with the third serotype. Cases are reported from Europe and North America. Disease can also occur in older adults. Treatment at this stage is largely supportive. Reported complications of neonatal cerebral infections include learning disabilities, epilepsy, and cerebral palsy.

Wolthers KC et al. Human parechoviruses as an important viral cause of sepsis-like illness and meningitis in young children. Clin Infect Dis. 2008 Aug 1;47(3):358–63. [PMID: 18558876]

Epidemic Louse-Borne Typhus

Essentials of Diagnosis

- Prodrome of headache, then chills and fever.
- Severe, intractable headaches, prostration, persisting high fever.
- Macular rash appearing on the fourth to seventh days

on the trunk and in the axillae, spreading to the rest of the body but sparing the face, palms, and soles.

- Diagnosis confirmed by specific antibodies using complement fixation, microagglutination, or immunofluorescence.

General Considerations

Epidemic louse-borne typhus is due to infection with *Rickettsia prowazekii*, a parasite of the body louse (Table 32–3). Transmission is favored by crowded, unsanitary living conditions, famine, war, or any circumstances that predispose to heavy infestation with lice. When the louse sucks the blood of a person infected with *R prowazekii*, the organism becomes established in the gut of the louse and grows there. When the louse is transmitted to another person (through contact or clothing) and has a blood meal, it defecates simultaneously, and the infected feces are rubbed into the itching bite wound or mucous membranes. Dry, infectious louse feces may also enter the respiratory tract. Cases can be acquired by travel to pockets of infection (eg, central and northeastern Africa, Central and South America). Recent outbreaks were reported from Peru, Burundi, and Russia. *R prowazekii* is considered a possible bioterrorist agent.

Table 32–3. Rickettsial diseases.

Disease	**Rickettsial Pathogen**	**Geographic Areas of Prevalence**	**Insect Vector**	**Mammalian Reservoir**	**Travel Association**
Typhus group					
Epidemic (louse-borne) typhus	*Rickettsia prowazekii*	South America, Central Africa	Louse	Humans, flying squirrels	Rare
Endemic (murine) typhus	*Rickettsia typhi*	Worldwide; small foci (United States: southeastern gulf coast)	Flea	Rodents	Often
Scrub typhus group					
Scrub typhus	*Orientia tsutsugamushi*	Southeast Asia, Japan, Australia, Western Siberia	Mite[1]	Rodents	Often
Spotted fever group					

Rocky Mountain spotted fever	*Rickettsia rickettsii*	Western Hemisphere; United States (especially mid-Atlantic coast region)	Tick[1]	Rodents, dogs	Rare
California flea rickettsiosis	*Rickettsia felis*	Worldwide?	Flea	Cats, opossums	
Mediterranean spotted fever, Boutonneuse fever, Kenya tick typhus, South African tick fever, Indian	*Rickettsia conorii*	Africa, India, Mediterranean regions	Tick[1]	Rodents, dogs	Often

tick typhus					
Queensland tick typhus	*Rickettsia australis*	Eastern Australia	Tick[1]	Rodents, marsupials	Often
Siberian Asian tick typhus	*Rickettsia sibirica*	Siberia, Mongolia	Tick[1]	Rodents	Rare
African tick bite fever	*Rickettsia africae*	Rural sub-Saharan Africa, Eastern Caribbean	Tick[1]	Cattle	Often
Rickettsialpox	*Rickettsia akari*	United States, Korea, former USSR	Mite[1]	Mice	
Other					
Ehrlichiosis and anaplasmosis,					

human					
Monocytic	*Ehrlichia chaffeensis, Anaplasma equi, Ehrlichia canis*	Southeastern United States	Tick[1]	Dogs	
Granulocytic	*Anaplasma phagocytophilum, Ehrlichia ewingii*	Northeastern United States	Tick[1]	Rodents, deer, sheep	
Q fever	*Coxiella burnetii*	Worldwide	None[2]	Cattle, sheep, goats	

[1] Also serve as arthropod reservoir by maintaining rickettsiae through transovarian transmission.

[2] Human infection results from inhalation of dust.

R prowazekii can survive in lymphoid tissues after primary infection, and years later, produce recrudescence of disease (Brill-Zinsser disease) without exposure to infected lice. This phenomenon can serve as a point source for future outbreaks.

An extrahuman reservoir of *R prowazekii* in the United States is flying squirrels. Transmission to humans can occur through their ectoparasites, usually causing atypical mild disease.

Clinical Findings

Symptoms and Signs

(Table 32–2.) Prodromal malaise, cough, headache, backache, arthralgia, and chest pain begin after an incubation period of 10–14 days, followed by an abrupt onset of chills, high fever, and prostration, with flu-like symptoms progressing to delirium and stupor. The headache is severe, and the fever is prolonged.

Other findings consist of conjunctivitis, hearing loss from neuropathy of the eighth cranial nerve, flushed facies, rales at the lung bases, and often splenomegaly. A macular rash (that may become confluent) appears first in the axillae and then over the trunk, spreading to the extremities but rarely involving the face, palms, or soles. In severely ill patients, the rash becomes hemorrhagic, and hypotension becomes marked. There may be acute kidney injury, stupor, and delirium. In spontaneous recovery, improvement begins 13–16 days after onset with a rapid drop of fever.

Laboratory Findings

The white blood cell count is variable. Thrombocytopenia, elevated liver enzymes, proteinuria and hematuria commonly occur. Serum obtained 5–12 days after onset of symptoms usually shows specific antibodies for R prowazekii antigens as demonstrated by complement fixation, microagglutination, or immunofluorescence. In primary rickettsial infection, early antibodies are IgM; in recrudescence (Brill disease), early antibodies are predominantly IgG. A PCR test is developed, but its availability is limited. R prowazekii is differentiated into 7 genotypes.

Imaging

Radiographs of the chest may show patchy consolidation.

Differential Diagnosis

The prodromal symptoms and the early febrile stage are not specific enough to permit diagnosis in nonepidemic situations. The rash is usually sufficiently distinctive for diagnosis, but it may be absent in up to 50% of cases or may be difficult to observe in dark-skinned persons. A variety of other acute febrile diseases should be considered, including typhoid fever, meningococcemia, and measles.

Brill-Zinsser disease (recrudescent epidemic typhus) has a more gradual onset than primary *R prowazekii* infection, fever and rash are of shorter duration, and the disease is milder and rarely fatal.

Complications

Pneumonia, thromboses, vasculitis with major vessel obstruction and gangrene, circulatory collapse, myocarditis, and uremia may occur.

Prevention

Prevention consists of louse control with insecticides, particularly by applying chemicals to clothing or treating it with heat, and frequent bathing. A deloused and bathed typhus patient is not infectious. The disease is not transmitted from person to person. Patients are infectious for the lice during the febrile period and perhaps 2–3 days after the fever returns to normal. Infected lice pass rickettsiae in their feces within 2–6 days after the blood meal and can be infectious earlier if crushed. Rickettsiae remain viable in a dead louse for weeks.

No vaccine is currently available for the prevention of *R prowazekii* infection. Past use of crude antigen or inactivated Rickettsia provided partial protection but was associated with undesirable toxic reactions and difficulties in standardization. Efforts to identify new candidate antigens through DNA technology are underway.

Treatment

Treatment consists of either doxycycline (100 mg orally twice daily for adults and children weighing > 45 kg, and 2.2 mg/kg twice daily for children weighing < 45 kg) or chloramphenicol (50–100 mg/kg/d in four divided doses, orally or intravenously; it is the drug of choice in pregnant women) for 4–10 days. In epidemic conditions, a single dose of doxycycline can be effective and is less costly.

Prognosis

The prognosis depends greatly on the patient's age and immune status. In children under age 10 years, the disease is usually mild. The mortality rate is 10% in the second and third decades but in the past reached 60% in the sixth decade.

Endemic Flea-Borne Typhus (Murine Typhus)

Rickettsia typhi, a ubiquitous pathogen recognized on all continents, is transmitted from rat to rat through the rat flea (Table 32–3). Humans usually acquire the infection in an urban or suburban setting when bitten by an infected flea, which releases infected feces while sucking blood. Rare human cases in the developed world follow travel, usually to Southeast Asia. Seroprevalence to R typhi among children in South Texas is reported as high as 14% and among the homeless in Houston about 10%.

Endemic typhus resembles recrudescent epidemic typhus in that it has a gradual onset, less severe symptoms, and a shorter duration of illness than epidemic typhus (7–10 days versus 14–21 days). The presentation is nonspecific, including fever, headache, and chills. Maculopapular rash occurs in around 50% of cases; it is concentrated on the trunk and fades fairly rapidly. Peripheral facial paralysis and splenic infarction are reported to occur. Severe disease with mental confusion and signs of hepatic, cardiac, renal, and pulmonary involvement may develop. Fatalities are uncommon but occur especially in the elderly. Jaundice, bradycardia, and the absence of a headache are correlated with a delayed defervescence (in both epidemic and endemic typhus).

The most common entity in the differential diagnosis is Rocky Mountain spotted fever, usually occurring after a rural exposure and with a different rash (centripetal versus centrifugal for endemic typhus). Serologic confirmation may be necessary for differentiation, with complement-fixing or immunofluorescent antibodies detectable within 15 days after onset, with specific *R typhi* antigens. A fourfold rise in serum antibody titers between the acute and the convalescence phase is diagnostic.

Preventive measures are directed at control of rats and ectoparasites (rat fleas) with insecticides, rat poisons, and rat-proofing of buildings. Antibiotic treatment is the same as for epidemic typhus (see above). Ciprofloxacin (500–750 mg orally twice a day) is another alternative in pregnant women.

Scrub Typhus (Tsutsugamushi Fever)

Essentials of Diagnosis

- Exposure to mites in endemic area of Southeast Asia, the western Pacific (including Korea), and Australia.
- Black eschar at site of the bite, with regional and generalized lymphadenopathy.
- Conjunctivitis and a short-lived macular rash.

- Frequent pneumonitis, encephalitis, and cardiac failure.

General Considerations

Scrub typhus is caused by *Orientia tsutsugamushi*, which is principally a parasite of rodents transmitted by mites in the endemic areas listed above (Table 32–3). The mites live on vegetation but complete their maturation cycle by biting humans who come in contact with infested vegetation. Vertical transmission occurs, and blood transfusions may transmit the pathogen as well. Rare occupational transmission via inhalation is documented among laboratory workers. The disease in endemic in Korea; China; Taiwan; Japan; Pakistan; India; Thailand; Malaysia; and Queensland, Australia.

Clinical Findings

Symptoms and Signs

After a 1- to 3-week incubation period, malaise, chills, severe headache, and backache develop. At the site of the bite, a papule evolves into a flat black eschar. The regional lymph nodes are enlarged and tender, and there may be generalized adenopathy. Fever rises gradually, and a macular rash appears primarily on the trunk after a week of fever and may be fleeting or may last a week. The patient may become obtunded. During the second or third week, pneumonitis, myocarditis and cardiac failure, encephalitis or meningitis, acute abdominal pain, granulomatous hepatitis, disseminated intravascular coagulation, acute respiratory distress syndrome, or acute kidney disease may develop, although not often. Gastrointestinal symptoms including nausea, vomiting, and diarrhea occur in nearly two-thirds of patients and correspond to the presence of superficial mucosal hemorrhage, multiple erosions, or ulcers in the gastrointestinal tract. An attack confers prolonged immunity against homologous strains and transient immunity against heterologous strains. Heterologous strains produce mild disease if infection occurs within a year after the first episode.

Laboratory Findings

Thrombocytopenia and elevation of liver enzymes, bilirubin, and creatinine are common. Serologic testing with immunofluorescence and immunoperoxidase assays or commercial dot-blot ELISA dipstick assays are convenient diagnostic aids, but a conclusive diagnosis requires documentation of a fourfold increase between acute and convalescence titers of antibodies. PCR (from the eschar or blood) may be the most sensitive diagnostic test while culture of the organism (by mouse inoculation) from blood obtained during the first few days of illness is another diagnostic modality. Unfortunately, both tests are of limited availability. A reticulonodular infiltrate is the most common finding on chest radiograph.

Differential Diagnosis

Leptospirosis, typhoid, dengue, malaria, hemorrhagic fevers, and other rickettsial infections should be considered. The headache may mimic trigeminal neuralgia. Scrub typhus is a recognized cause of obscure tropical fevers, especially in children.

Prevention

Repeated application of long-acting miticides can make endemic areas safe. Insect repellents on clothing and skin provide some protection. For short exposure, chemoprophylaxis with doxycycline (200 mg weekly) can prevent the disease but permits infection. No effective vaccines are available.

Treatment & Prognosis

Without treatment, fever subsides spontaneously after 2 weeks, but the mortality rate may be 10–30%. Empiric treatment for 3 days with doxycycline, 100 mg orally twice daily, or for 7 days with chloramphenicol, 25 mg/kg/d orally or intravenously in four divided doses, eliminates most deaths and relapses. Chloramphenicol- and tetracycline-resistant strains have been reported from Southeast Asia, where azithromycin or roxythromycin may become the drug of choice for children, pregnant women, and patients with refractory disease. Rifampin reduces the duration of fever by 1 day when used with doxycycline. HIV infection does not appear to influence the severity of scrub typhus.

Rocky Mountain Spotted Fever

Essentials of Diagnosis

- Exposure to tick bite in an endemic area.
- An influenza-like prodrome followed by chills, fever, severe headache, myalgias, restlessness, and prostration; occasionally, delirium and coma.
- Red macular rash appears between the second and sixth days of fever, first on the wrists and ankles and then spreading centrally; it may become petechial.
- Serial serologic examinations by indirect fluorescent antibody (IFA) confirm the diagnosis retrospectively.

General Considerations

Despite its name, most cases of Rocky Mountain spotted fever (RMSF) occur outside the Rocky Mountain area. Passive surveillance data from 1997 to 2002 reported cases of RMSF from each of the contiguous states except Vermont and Maine. More than half (56%) of these cases were from only five states: North Carolina, South Carolina, Tennessee, Oklahoma, and Arkansas (see illustration). The causative agent, *R rickettsii*, is transmitted to humans by the bite of ticks, including the Rocky Mountain wood tick, *D andersoni*, in the western United States, and the American dog tick, *Dermacentor variabilis*, in the eastern United States. The brown dog tick, *Rhipicephalus sanguineus*, is a vector in eastern Arizona. In the United States, the estimated annual incidence of RMSF is 2.2 cases per million persons with cases primarily occurring from April through September, and with a higher incidence among children and men.

Fig.

Average annual incidence of Rocky Mountain spotted fever according to county in the United States, 1981-1992. (Reproduced, with permission, from Dalton MJ et al: National surveillance for Rocky Mountain spotted fever, 1981-1992: epidemiologic summary and evaluation of risk factors for fatal outcome. Am J Trop Med Hyg 1995;52:405.)

Other hard ticks transmit the organism in the southern United States and in Central and South America and are responsible for transmitting it among rodents, dogs, porcupines, and other animals.

Clinical Findings

Symptoms and Signs

Two to 14 days (mean, 7 days) after the bite of an infectious tick, symptoms begin with fever, chills, headache, nausea and vomiting, myalgias, restlessness, insomnia, and irritability. Cough and pneumonitis may develop. Delirium, lethargy, seizures, stupor, and coma may appear (see micrograph). The face is flushed and the conjunctiva injected (Plate 99). The rash (faint macules that progress to maculopapules and then petechiae) appears between days 2 and 6 of fever, first on the wrists and ankles, spreading centrally to the arms, legs, and trunk for 2–3 days; involvement of the palms and soles is characteristic. About 10% of cases, however, occur without rash or with minimal rash. In some cases there is splenomegaly, hepatomegaly, jaundice, myocarditis (which may mimic an acute coronary syndrome), or uremia. ARDS and necrotizing vasculitis are of greatest concern.

Copyright © 1997 by the Massachusetts Medical Society. All rights reserved.)

Plate 99.

Hard palate lesion caused by Rocky Mountain spotted fever. (Public Health Image Library, CDC.)

Laboratory Findings

Thrombocytopenia, hyponatremia, elevated aminotransferases, and hyperbilirubinemia are common. Cerebrospinal fluid may show hypoglycorrhachia and mild pleocytosis. Disseminated intravascular coagulation is observed in severe cases. Diagnosis during the acute phase of the illness can be made by immunohistologic demonstration of *R rickettsiae* in skin biopsy specimens, but this must be performed as soon as skin lesions become apparent and before antibiotics are started to achieve maximum sensitivity. Isolation of the organism using the shell-vial technique is available in some laboratories but is hazardous.

Serologic studies confirm the diagnosis, but most patients do not mount an antibody response until the second week of illness. The indirect fluorescent antibody test is most commonly used. No PCR technique has been validated for clinical use.

Differential Diagnosis

The diagnosis is challenging. Up to 40% of patients do not recall a tick bite, and initial diagnosis is made clinically. Early symptoms may resemble those of many other infections. The rash may be confused with that of measles, typhoid, and ehrlichiosis, or—most importantly—meningococcemia. Blood cultures and examination of cerebrospinal fluid establish the latter.

Prevention

Protective clothing, tick-repellent chemicals, and the removal of ticks at frequent intervals are helpful measures. Prophylactic therapy after a tick bite is not currently recommended.

Treatment & Prognosis

Treatment with doxycycline or, in pregnant women, chloramphenicol at similar doses and duration as for epidemic typhus (see above) is recommended. Patients usually defervesce within 48–72 hours. Therapy should be maintained for at least 3 days after defervescence. Mild cases in low-risk individuals may be observed without treatment.

Although the reported mortality rate in the United States is about 3–5%, it can be as high as 70% in the untreated elderly. Myocarditis is the leading cause of death. Other risk factors for a fatal outcome include very young age, atypical clinical features (absence of headache, no history of tick attachment, gastrointestinal symptoms), underlying chronic diseases, and a delay in initiation of appropriate antibiotic therapy. The usual cause of death is pneumonitis with respiratory or cardiac failure. Sequelae, more common than formerly recognized, may include seizures, encephalopathy, peripheral neuropathy, paraparesis, bowel and bladder incontinence, cerebellar and vestibular dysfunction, hearing loss, and motor deficits.

Cunha BA. Clinical features of Rocky Mountain spotted fever. Lancet Infect Dis. 2008 Mar;8(3):143–4. [PMID: 18291332]

Rickettsialpox

Rickettsia akari is a parasite of mice, transmitted by mites *Liponyssoides sanguineus* (Table 32–2). Rickettsialpox occurs in humans when crowded conditions and mouse-infested housing allow transmission of the pathogen to humans. In a free clinic in downtown Los Angeles, California, serologic evidence of infection was detected in 8% of patients. The incubation period is 7–12 days. Onset is sudden, with chills, fever, headache, photophobia, and disseminated aches and pains. The primary lesion is a painless red papule that vesiculates and forms a black eschar. Two to 4 days after onset of symptoms, a widespread papular eruption appears that becomes vesicular and forms crusts that are shed in about 10 days. Early lesions may resemble those of chickenpox (typically vesicular versus papulovesicular in rickettsialpox). Pathologic findings include dermal edema, subepidermal vesicles, and at times a lymphocytic vasculitis.

Transient leukopenia and thrombocytopenia and acute hepatitis can occur. A fourfold rise in serum antibody titers to rickettsial antigen, detected by complement fixation or indirect fluorescent assays, is diagnostic.

Conjugated antirickettsial globulin can identify antigen in punch biopsies of skin lesions. PCR detection of rickettsial DNA in fresh tissue also appears of value. *R akari* is also reported to be isolable from eschar biopsy specimens.

Treatment includes doxycycline (200 mg/d) for 7 days. The disease is usually mild and self-limited without treatment, but occasionally severe symptoms may require hospitalization. Control requires the elimination of mice from human habitations and insecticide applications to suppress the mite vectors.

Bennett SG et al. Serologic evidence of a *Rickettsia akari*-like infection among wild-caught rodents in Orange County and humans in Los Angeles County, California. J Vector Ecol. 2007 Dec;32(2):198–201. [PMID: 18260508]

Tick Typhus (Rickettsial Fever)

The term "tick typhus" denotes a variety of spotted rickettsial fevers. They are often named by geography, eg, Mediterranean spotted fever, Queensland tick typhus, Oriental spotted fever, African tick bite fever, Siberian tick typhus, North Asian tick typhus, or by morphology, eg, boutonneuse fever. These illnesses are transmitted by tick vectors of the rickettsial organisms *R conorii, R australis, R japonica, R africae*, and *R sibirica* (Table 32–

3). Dogs and wild animals, usually rodents but even reptiles, may serve as reservoirs. Travel is a risk factor for disease, particularly among elderly ecotourists. The pathogens usually produce an eschar or black spot (tâche noire) at the site of the tick bite that may be useful in diagnosis, though spotless boutonneuse fever occurs. Symptoms include fever, headache, myalgias, and rash. Rarely, papulovesicular lesions may resemble rickettsialpox. Endothelial injury produces perivascular edema and dermal necrosis. Regional adenopathy, disseminated lesions, kidney disease, splenic rupture, and focal hepatic necrosis may occur. Diabetes, dehydration, and uremia were risk factors for mortality in one series. The disease occurs among travelers, the most common travel-associated rickettsiosis being African tick bite fever. Diagnosis is clinical, with serologic or PCR confirmation. Prevention entails protective clothing, repellents, and inspection for and removal of ticks. Treatment is with the following drugs given for 7–10 days: doxycycline (200 mg/d), chloramphenicol (50–75 mg/kg/d in four divided doses), or ciprofloxacin (500 mg twice daily). The combination of erythromycin and rifampin is effective and safe in pregnancy. Delayed therapy is the usual cause of morbidity.

Another rickettsial infection, formerly classified as an endemic or murine typhus, is more properly classified as a spotted fever. The causative agent, *R felis,* is an organism that has been linked to the cat flea and opossum exposures. Most cases in the United States occur in the spring and summer, are reported from southern Texas and California; it also appears to be present in Hawaii. Cases are treated as above.

Ehrlichiosis & Anaplasmosis

Essentials of Diagnosis

- Infection of monocyte or granulocyte by tick-borne gram-negative bacteria.
- Nine-day incubation period, with variable clinical illness, ranging from asymptomatic to persistent or life-threatening.
- Common symptoms are malaise, nausea, fever, and headaches.
- Excellent response to therapy with tetracyclines.

General Considerations

Ehrlichiae and anaplasmae are small tick-borne gram-negative obligate intracellular bacteria that infect monocytes or granulocytes. Human monocytic ehrlichiosis is caused by *Ehrlichia chaffeensis* (Table 32–3). Human granulocytic anaplasmosis is caused by *Anasplasma phagocytophilium. Ehrlichia ewingii* (infecting primarily dogs) can rarely cause human granulocytic ehrlichiosis similar to human granulocytic anaplasmosis. Another ehrlichia-like organism, *Neorickettsia sennetsu,* is the etiologic agent of sennetsu fever, which is confined to western Japan.

Human monocytic ehrlichiosis is seen primarily in the Southeast, mid-Atlantic, and South Central states of the United States, though cases are also recognized in Israel, Japan, Mexico, South America, and Europe. Human granulocytic anaplasmosis is more frequent in Northeastern and Midwestern United States; but infections in Europe and China are also well documented. Human infection with *Eewingii* is limited to Missouri, Oklahoma, and Tennessee and occurs mainly among the immunocompromised. In North America, the major vectors for these pathogens are the Lone Star tick (*Amblyomma americanus* for *E chaffeensis* and *E ewingii*), the western black-legged tick (*Ixodes pacificus,* for E chaffeensis), and *Ixodes scapularis* (the same vector for Lyme disease and babesiosis) for *A phagocytophilium*). Reported incidences of both human monocytic and granulocytic ehrlichiosis are about 0.6 and 1.4 per million, respectively, with higher rates in the summer. The highest attack rate is in men over 60 years of age.

The principal reservoirs for human monocytic ehrlichiosis and human granulocytic anaplasmosis are the white tail deer and the white footed mouse, respectively. Other mammals can be implicated as well. A nosocomial outbreak was recently reported from China. Perinatal transmission of human granulocytic anaplasmosis is also documented.

Clinical Findings

Symptoms and Signs

Clinical disease of human monocytic ehrlichiosis ranges from mild to life-threatening. Typically, after about a 9-day incubation period and a prodrome consisting of malaise, rigors, and nausea, worsening fever and headache develop. A pleomorphic rash may occur. The presentation in immunosuppressed patients and the elderly tends to be more severe than in immunocompetent and younger patients. Serious sequelae include acute respiratory failure and ARDS, encephalopathy, and acute kidney disease, which may mimic thrombotic thrombocytopenic purpura.

The symptoms of human granulocytic ehrlichiosis and *E ewingii* infection are similar to those seen with human monocytic ehrlichiosis. Rash, however, is infrequent in human granulocytic ehrlichiosis and should prompt the consideration of other infections (eg, Lyme disease). Persistent fever and malaise are reported to occur for 2 or more years. Coinfection with Lyme disease or basesiosis may occur. (See micrograph.)

Fig.

Rocky Mountain spotted fever. Inflamed wall of blood vessel with focal destruction (arrows) and leakage of proteins into adjacent white matter (Luxol fast blue-hematoxylin and eosin, x190). (Reproduced, with permission, from Samuels M: Case records of the Massachusetts General Hospital. Weekly clinicopathological exercises. Case 32–1997: A 43-year-old woman with rapidly changing pulmonary infiltrates and markedly increased intracranial pressure. N Engl J Med 1997;337:1155. Copyright © 1997 by the Massachusetts Medical Society. All rights reserved.)

Laboratory Findings

Diagnosis can be made by the history of tick exposure followed by a characteristic clinical presentation. Leukopenia, absolute lymphopenia, thrombocytopenia, and transaminitis occur often. Thrombocytopenia occurs more often than leukopenia in human granulocytic ehrlichiosis. Examination of peripheral blood with Giemsa stain may reveal characteristic intraleukocytic vacuoles (morulae). An indirect fluorescent antibody assay is available through the CDC and requires acute and convalescent sera. A PCR assay, if available, is a rapid diagnostic tool, especially for early disease.

Treatment

Treatment for both forms of ehrlichiosis is with doxycycline, 100 mg twice daily (orally or intravenously) for at least 10 days or until 3 days of defervescence. Rifampin is an alternative in pregnant women and children. Treatment should not be withheld while awaiting confirmatory serology when suspicion is high. Lack of clinical improvement and defervescence 48 hours after doxycycline initiation suggests an alternate diagnosis.

Q Fever

Essentials of Diagnosis

- Exposure to sheep, goats, cattle, or their products is common; some infections are laboratory acquired.
- An acute or chronic febrile illness with severe headache, cough, prostration, and abdominal pain.
- Extensive pneumonitis, hepatitis, or encephalopathy; less often, endocarditis, vascular infections, or chronic fatigue syndrome.
- A common cause of culture-negative endocarditis.

General Considerations

*Q fever (*for "query" in view of its formerly unknown cause) is a reportable disease in the United States caused by *Coxiella burnetii*, an organism previously classified as a rickettsia but now considered a proteobacteria. Unlike rickettsiae, C burnetii is usually transmitted to humans not by arthropods but by inhalation or ingestion. *Coxiella* infections occur mostly in cattle, sheep, and goats, in which they cause mild or subclinical disease (Table 32–3). In these animals, reactivation of the infection occurs during pregnancy and causes abortions or low birth weight offspring. *Coxiella* is resistant to heat and drying and remains infective in the environment for months. Humans become infected by inhalation of aerosolized bacteria (in dust or droplets) from feces, urine, milk, or products of conception of infected animals. Ingestion and skin penetration are recognized routes of transmission as well. Outbreaks associated with other mammals such as cats and dogs are also described. There is an occupational risk for animal handlers, slaughterhouse workers, veterinarians, laboratory workers, and other workers exposed to animal products. Outbreaks in military personnel returning from Iraq and Afghanistan were recently described. Endocarditis, an uncommon but serious form of *Coxiella* infection, has been linked to preexisting valvular conditions, immunocompromise, urban residence, and raw milk ingestion. Horizontal spread from one human to another does not seem to occur even in the presence of florid pneumonitis, but maternal–fetal infection can occur.

Clinical Findings

Symptoms and Signs

Asymptomatic infection is common. For the remaining cases, a febrile illness develops after an incubation period of 1–3 weeks, usually accompanied by headache, prostration, and muscle pains. The clinical course may be acute, chronic (duration 6 months), or relapsing. Pneumonia and granulomatous hepatitis are the predominant manifestation in the acute form, whereas other less common manifestations include skin rashes (maculopapular or purpuric), fever of unknown origin, myocarditis, pericarditis, aseptic meningitis, encephalitis, hemolytic anemia, orchitis, acute kidney disease, spondylodiscitis, tenosynovitis, and regional (mediastinal) or diffuse lymphadenopathies. The most common presentation of chronic Q fever is culture-negative endocarditis, which occurs in less than 1% of infected individuals. It is found mainly in the setting of preexisting valve disease. Vascular infections, particularly of the aorta (and potentially causing aneurysms) are the second most common form of Q fever and are associated with a high mortality (25%). A Q fever chronic fatigue syndrome is thought by some experts to involve bacteremic shedding from bone marrow reservoirs and to be immunogenetically determined.

Reactivation of Q fever in pregnant women may cause spontaneous abortions, intrauterine growth retardation, intrauterine fetal death, premature delivery, and oligamnios.

Laboratory Findings

Laboratory examination during the acute phase may show elevated liver function tests and occasional leukocytosis. Patients with acute Q fever usually produce antibodies to *C burnetii* phase II antigen. A fourfold rise between acute and convalescent sera by indirect immunofluorescence is diagnostic.

The diagnosis of chronic Q fever is established on the basis of serologic tests done at 3- and 6-month intervals. The IgG titer against phase I antigen is usually 1:200 or greater. In some cases, the diagnosis is not made until the time of valve replacement, with PCR of tissue samples. Isolation of *C burnetii* from affected valves is also possible using the shell-vial technique, but the organism is highly transmissible to laboratory workers and culture techniques should be carried out in biosafety level 3 settings.

Imaging

Radiographs of the chest show patchy pulmonary infiltrates, often more prominent than the physical signs would suggest.

Differential Diagnosis

Viral, mycoplasmal, and bacterial pneumonias, viral hepatitis, brucellosis, tuberculosis, psittacosis, and other animal-borne diseases must be considered. Q fever should be considered in cases of unexplained fevers with negative blood cultures in association with embolic or cardiac disease.

Prevention

Prevention is based on detection of the infection in livestock, reduction of contact with infected animals or dusts contaminated by them, special care when working with animal tissues, and effective pasteurization of milk. No Q fever vaccine is approved for use in the United States, although a whole-cell vaccine, with a 5-year efficacy of more than 95%, is available in Australia for persons with high-risk exposures.

C burnetii is category B bioterrorism agent. In the setting of a bioterrorist attack, postexposure prophylaxis should be started 8–12 days after exposure, doxycycline (100 mg orally twice daily) should be taken for 5 days, and a pregnant woman should take trimethoprim-sulfamethoxazole (160 mg/800 mg twice daily) for the duration of the pregnancy.

Treatment & Prognosis

For acute infection, treatment with doxycycline (100 mg orally twice daily) for 14 days or at least 3 full days after defervescence is recommended. Even in untreated patients, the mortality rate is usually low, except when endocarditis develops.

For the treatment of endocarditis, most experts recommend a combination of oral doxycycline (200 mg/d) plus oral hydroxychloroquine (600 mg/d) for at least 2 years. Serologic responses can be monitored to determine cessation of therapy. Heart valve replacement may be necessary in refractory disease. Given the difficulty in treating endocarditis, transthoracic echocardiography is recommended for all patients with acute Q fever, and the same aforementioned therapy for 1 year should be offered if a valvulopathy is observed.

Because of the many and serious obstetric complications that occur among pregnant women in whom Q fever develops (listed above), a regimen of long-term trimethoprim-sulfamethoxasole (320/1600 mg for at least 5 weeks) should be given to all infected, pregnant women.

Kawasaki Disease

Essentials of Diagnosis

- Fever, bilateral conjunctivitis, oral mucosal changes, rash, cervical lymphadenopathy, peripheral extremity changes.
- Elevated erythrocyte sedimentation rate and C-reactive protein levels.

General Considerations

Kawasaki disease is a worldwide multisystemic disease initially described by Tomisaku Kawasaki in 1967. It is also known as the "mucocutaneous lymph node syndrome." It occurs mainly in children between the ages of 3 months and 5 years but can occur occasionally in adults as well. Kawasaki disease occurs more frequently in Asians or Pacific Islanders but rarely in whites. It is a vasculitis characterized by the infiltration of vessel walls with mononuclear cells and later by IgA secreting plasma cells that can result in the destruction of the media and aneurysm formation. Several infectious agents (New Haven coronavirus, parvovirus, bocavirus, CMV, *Yersinia pseudotuberculosis*), bacterial superantigens, and genetic polymorphisms in components of the immune system have been implicated in its pathogenesis.

Clinical Findings

A clinical diagnosis of "complete" Kawasaki disease requires, in the absence of other processes, explaining the current illness of fever and four of the following criteria for at least 5 days: bilateral nonexudative conjunctivitis, mucous membrane changes of at least one type (injected pharynx, erythema, swelling and fissuring of the lips, strawberry tongue), peripheral extremity changes of at least one type (edema, desquamation, erythema of the palms and soles, induration of the hands and feet, Beau lines [transverse grooves of the nails]), a polymorphous rash, and cervical lymphadenopathy greater than 1.5 cm. An "incomplete" form is diagnosed when only two criteria are met.

A major complication is arteritis of the coronary vessels, occurring in about 25% of untreated patients, on occasion causing myocardial infarction. It is more common among patients over 6 years or below 1 year of age. Noninvasive diagnosis of this complication can be made with magnetic resonance angiography or transthoracic echocardiography. Other factors associated with the development of coronary aneurysms are relentless fever (after the administration of IVIG), high C-reactive protein, anemia, hypoalbuminemia, hyponatremia, thrombocytopenia, and male gender. Pericardial effusions, myocarditis, and mitral regurgitation (usually mild) are also common. Arteritis of extremity vessels, peripheral gangrene, syndrome of inappropriate secretion of antidiuretic hormone (SIADH), and the hemophagocytic syndrome are also reported. Cerebrospinal fluid pleocytosis is found in one-third of cases.

Differentiation from disseminated adenovirus infection is important and can be performed with rapid adenovirus assays.

Treatment

Every patient with a clinical diagnosis of Kawasaki disease (complete or incomplete) should be treated. IVIG (2 g/kg over 10–12 hours) is given within the first 10 days of illness. For those presenting later, but with persistent fever, ongoing systemic inflammation, or aneurysm formation, IVIG should be offered as well. Concomitant aspirin should be started at 80–100 mg/kg/d (divided into four doses and not exceeding 4 g/d) until the patient is afebrile for 48 hours and then reduced to 3–5 mg/kg/d until markers of acute inflammation normalize. Aspirin therapy is continued if coronary aneurysm develops. If fevers persist beyond 36 hours after the initial IVIG infusion, a new dose of 2 g/kg should be given if no other source of fever is found. Methylprednisolone (30 mg/kg/d for a maximum of 3 days) should follow if the disease persists after the second IVIG administration. Further options for refractory cases include TNF- blockers (eg, infliximab), cyclophosphamide, methotrexate, and plasmapheresis. An echocardiogram is essential in the acute phase of illness and 6–8 weeks after onset. Warfarin is indicated along with low-dose aspirin in patients with aneurysms larger than 8 mm in diameter. If myocardial infarction occurs, therapy with thrombolytics, percutaneous coronary intervention, coronary artery bypass grafts, and even cardiac transplantation should be considered. Manifestation of coronary aneurysms can occur as late as in the third or fourth decade of life and regular follow-up with a cardiologist is recommended for those with coronary complications.

When to Refer

All cases of Kawasaki disease merit referral to specialists.

Pharyngitis

Essentials of Diagnosis

- Abrupt onset of sore throat, fever, malaise, nausea, and headache.
- Throat red and edematous, with or without exudate; cervical nodes tender.
- Diagnosis confirmed by culture of throat.

General Considerations

Group A -hemolytic streptococci *(Streptococcus pyogenes)* are the most common bacterial cause of pharyngitis. Transmission occurs by droplets of infected secretions. Group A streptococci producing erythrogenic toxin may cause scarlet fever in susceptible persons.

Clinical Findings

Symptoms and Signs

"Strep throat" is characterized by a sudden onset of fever, sore throat, pain on swallowing, tender cervical adenopathy, malaise, and nausea. The pharynx, soft palate, and tonsils are red and edematous. There may be a purulent exudate. The Centor clinical criteria for the diagnosis of streptococcal pharyngitis are temperature > 38 °C, tender anterior cervical adenopathy, lack of a cough, and pharyngotonsillar exudate.

The rash of scarlet fever is diffusely erythematous, resembling a sunburn, with superimposed fine red papules, and is most intense in the groin and axillas. It blanches on pressure, may become petechial, and fades in 2–5 days, leaving a fine desquamation. The face is flushed, with circumoral pallor, and the tongue is coated with enlarged red papillae (strawberry tongue).

Laboratory Findings

Leukocytosis with neutrophil predominance is common. Throat culture onto a single blood agar plate has a sensitivity of 80–90%. Rapid diagnostic tests based on detection of streptococcal antigen are slightly less sensitive than culture.

Complications

Suppurative complications include sinusitis, otitis media, mastoiditis, peritonsillar abscess, and suppuration of cervical lymph nodes.

Nonsuppurative complications are rheumatic fever and glomerulonephritis. Rheumatic fever may follow recurrent episodes of pharyngitis beginning 1–4 weeks after the onset of symptoms. Glomerulonephritis follows a single infection with a nephritogenic strain of streptococcus group A (eg, types 4, 12, 2, 49, and 60), more commonly on the skin than in the throat, and begins 1–3 weeks after the onset of the infection.

Differential Diagnosis

Streptococcal sore throat resembles (and cannot be reliably distinguished clinically from) pharyngitis caused by adenoviruses, Epstein-Barr virus, *Arcanobacterium haemolyticum* (which also may cause a rash), and other agents. Pharyngitis and lymphadenopathy are common findings in primary HIV infection. Generalized lymphadenopathy, splenomegaly, atypical lymphocytosis, and a positive serologic test distinguish mononucleosis from streptococcal pharyngitis. Diphtheria is characterized by a pseudomembrane; candidiasis shows white patches of exudate and less erythema; and necrotizing ulcerative gingivostomatitis (Vincent fusospirochetal gingivitis or stomatitis) presents with shallow ulcers in the mouth. Retropharyngeal abscess or bacterial epiglottitis should be considered when odynophagia and difficulty in handling secretions are present and when the severity of symptoms is disproportionate to findings on examination of the pharynx.

Treatment

Antimicrobial therapy has a modest effect on resolution of symptoms and primarily is administered for prevention of complications. Antibiotic therapy can be safely delayed until the diagnosis is established on the basis of a positive antigen test or culture. Empiric therapy usually is not a cost-effective approach to the management of most adults with pharyngitis because in typical clinical settings, the prevalence of streptococcal pharyngitis is likely to be no more than 10–20% and the positive predictive value of clinical criteria is low. Clinical criteria, such as the Centor criteria, are useful for identifying patients in whom a rapid antigen test or throat culture is indicated. Patients who meet two or more of these criteria merit further testing. When three of the four are present, laboratory sensitivity of rapid antigen testing exceeds 90%. When only one criterion is present, streptococcal pharyngitis is unlikely. In high-prevalence settings or if clinical suspicion for streptococcal pharyngitis is high, a negative antigen test or culture should be confirmed by a follow-up culture.

Benzathine Penicillin G

Benzathine penicillin G, 1.2 million units intramuscularly as a single dose, is optimal therapy.

Penicillin VK

Penicillin VK, 500 mg orally four times a day (or amoxicillin, 750 mg orally twice daily) for 10 days, is effective, but compliance may be poor after the patient becomes asymptomatic in 2–4 days.

Cephalosporins

Cefdinir, 300 mg orally twice daily for 5–10 days or 600 mg orally once daily for 10 days, and cefpodoxime, 100 mg orally twice daily for 5–10 days, are both approved by the US Food and Drug Administration (FDA) for the treatment of streptococcal pharyngitis but should be reserved for penicillin-allergic patients able to tolerate cephalosporins.

Macrolides

Erythromycin, 500 mg orally four times a day, or azithromycin, 500 mg orally once daily for 3 days, is an alternative for the penicillin-allergic patient. Macrolides are less effective than penicillins and are considered second-line agents. Macrolide-resistant strains almost always are susceptible to clindamycin, a suitable alternative to penicillins; a 10-day course of 300 mg orally twice daily is effective.

Prevention of Recurrent Rheumatic Fever

Effectively controlling rheumatic fever depends on identification and treatment of primary streptococcal infection and secondary prevention of recurrences. Patients who have had rheumatic fever should be treated with a continuous course of antimicrobial prophylaxis for at least 5 years. Effective regimens are erythromycin, 250 mg orally twice daily, or penicillin G, 500 mg orally daily.

Streptococcal Skin Infections

Group A -hemolytic streptococci are not normal skin flora. Streptococcal skin infections result from colonization of normal skin by contact with other infected individuals or by preceding streptococcal respiratory infection.

Clinical Findings

Symptoms and Signs

Impetigo is a focal, vesicular, pustular lesion with a thick, amber-colored crust with a "stuck-on" appearance.

Erysipelas is a painful superficial cellulitis that frequently involves the face. It is well demarcated from the surrounding normal skin. It affects skin with impaired lymphatic drainage, such as edematous lower extremities or wounds.

Laboratory Findings

Cultures obtained from a wound or pustule are likely to grow group A streptococci. Blood cultures are occasionally positive.

Treatment

Parenteral antibiotics are indicated for patients with facial erysipelas or evidence of systemic infection. Penicillin, 2 million units intravenously every 4 hours, is the drug of choice. However, staphylococci infections may at times be difficult to differentiate from streptococcal infections. In practice, initial therapy for patients with risk factors for *Staphylococcus aureus* (eg, injection drug use, diabetes, wound infection) should cover this organism. Nafcillin, 1.5 g every 6 hours intravenously, and cefazolin, 1 g intravenously or intramuscularly every 8 hours, are reasonable choices. In the patient at risk for methicillin-resistant *S aureus* infection or with a serious penicillin allergy (ie, anaphylaxis), vancomycin, 1000 mg intravenously every 12 hours, should be used.

Patients who do not require parenteral therapy may be treated with amoxicillin, 750 mg twice daily for 7–10 days. A first-generation oral cephalosporin, eg, cephalexin, 500 mg four times daily, or clindamycin, 300 mg orally three times daily, is an alternative to amoxicillin.

Other Group A Streptococcal Infections

Arthritis, pneumonia, empyema, endocarditis, and necrotizing fasciitis are relatively uncommon infections that may be caused by group A streptococci. Toxic shock-like syndrome also occurs.

Arthritis generally occurs in association with cellulitis. In addition to intravenous therapy with penicillin G, 2 million units every 4 hours (or cefazolin or vancomycin in doses recommended above for penicillin-allergic patients), frequent percutaneous needle aspiration should be performed to remove joint effusions. Open surgical drainage may be necessary when the hip or shoulder is infected.

Pneumonia and **empyema** often are characterized by extensive tissue destruction and an aggressive, rapidly progressive clinical course associated with significant morbidity and mortality. High-dose penicillin and chest tube drainage are indicated for treatment of empyema. Vancomycin is an acceptable substitute in penicillin-allergic patients.

Group A streptococci can cause **endocarditis.** Endocarditis should be treated with 4 million units of penicillin G intravenously every 4 hours for 4–6 weeks. Vancomycin, 1 g intravenously every 12 hours, is recommended for persons allergic to penicillin.

Necrotizing fasciitis is a rapidly spreading infection involving the fascia of deep muscle. The clinical findings at presentation may be those of severe cellulitis, but the presence of systemic toxicity and severe pain, which may be followed by anesthesia of the involved area due to destruction of nerves as infection advances through the fascial planes, is a clue to the diagnosis. Surgical exploration is mandatory when the diagnosis is suspected. Early and extensive debridement is essential for survival.

Any streptococcal infection—and necrotizing fasciitis in particular—can be associated with **streptococcal toxic shock syndrome**, typified by invasion of skin or soft tissues, acute respiratory distress syndrome, and kidney failure. The very young, the elderly, and those with underlying medical conditions are at particularly high risk for invasive disease. Bacteremia occurs in most cases. Skin rash and desquamation may not be present. Mortality rates can be up to 80%. The syndrome is due to elaboration of pyrogenic erythrotoxin (which also causes **scarlet fever**), a superantigen that stimulates massive release of inflammatory cytokines believed to mediate the shock. A -lactam remains the drug of choice for treatment of serious streptococcal infections, but clindamycin, which is a potent inhibitor of toxin production, should also be administered at a dose of 600 mg every 8 hours intravenously for invasive disease, especially in the presence of shock. Intravenous immune globulin has also been recommended for streptococcal toxic shock syndrome for presumed, although unproven, therapeutic benefit from specific antibody to streptococcal exotoxins in immune globulin preparations. Two dosage regimens have been used: 450 mg/kg once daily for 5 days or a single dose of 2 g/kg with a repeat dose at 48 hours if the patient remains unstable.

Outbreaks of invasive disease have been associated with colonization by invasive clones that can be transmitted to close contacts who, though asymptomatic, may be a reservoir for disease. Tracing contacts of patients with invasive disease is controversial.

diagnosis and management. Clin Infect Dis. 2007 Mar 1;44(5):705–10. [PMID: 17278065]

Eisenstein BI. Treatment challenges in the management of complicated skin and soft-tissue infections. Clin Microbiol Infect. 2008 Mar;14(Suppl 2):17–25. [PMID: 18226086]

Non-Group A Streptococcal Infections

Non-group A hemolytic streptococci (eg, groups B, C, and G) produce a spectrum of disease similar to that of group A streptococci. The treatment of infections caused by these strains is the same as for group A streptococci.

Group B streptococci are an important cause of sepsis, bacteremia, and meningitis in the neonate. Antepartum screening to identify carriers and peripartum antimicrobial prophylaxis are recommended in pregnancy. This organism, part of the normal vaginal flora, may cause septic abortion, endometritis, or peripartum infections and, less commonly, cellulitis, bacteremia, and endocarditis in adults. Treatment of infections caused by group B streptococci is with either penicillin or vancomycin in doses recommended for group A streptococci. Because of in vitro synergism, some experts recommend the addition of low-dose gentamicin, 1 mg/kg every 8 hours.

Viridans streptococci, which are nonhemolytic or -

hemolytic (ie, producing a green zone of hemolysis on blood agar), are part of the normal oral flora. Although these strains may produce focal pyogenic infection, they are most notable as the leading cause of native valve endocarditis (see below).

Group D streptococci include *Streptococcus bovis* and the enterococci. *S bovis* is a cause of endocarditis in association with bowel neoplasia or cirrhosis and is treated like viridans streptococci.

Larsen JW et al. Group B Streptococcus and pregnancy: a review. Am J Obstet Gynecol. 2008 Apr;198(4):440–8. [PMID: 18201679]

Enterococcal Infections

Two species, *Enterococcus faecalis* and *Enterococcus faecium*, are responsible for most human enterococcal infections. Enterococci cause wound infections, urinary tract infections, bacteremia, and endocarditis. Infections caused by penicillin-susceptible strains should be treated with penicillin 3–4 million units every 4 hours; ampicillin 3 g every 6 hours; or if the patient is penicillin-allergic, vancomycin 15 mg/kg every 12 hours intravenously. If the patient has endocarditis or meningitis, gentamicin 1 mg/kg every 8 hours intravenously should be added to the regimen in order to achieve the bactericidal activity that is required to cure these infections.

Resistance to vancomycin, penicillin, and gentamicin is common among enterococcal isolates, especially *E faecium;* it is essential to determine antimicrobial susceptibility of isolates. Infection control measures that may be indicated to limit their spread include isolation, barrier precautions, and avoidance of overuse of vancomycin and gentamicin. Consultation with an infectious diseases specialist is strongly advised when treating infections caused by resistant strains of enterococci. Quinupristin/dalfopristin and linezolid are approved by the FDA for treatment of infections caused by vancomycin-resistant strains of enterococci. Quinupristin/dalfopristin is not active against strains of *E faecalis* and should be used only for infections caused by *E faecium.* The dose is 7.5 mg/kg intravenously every 8–12 hours. Phlebitis and irritation at the infusion site (often requiring a central line) and an arthralgia-myalgia syndrome are relatively common side effects. Linezolid, an oxazolidinone, is active against both *E faecalis* and *E faecium.* The dose is 600 mg twice daily, and both intravenous and oral preparations are available. Its two principal side effects are thrombocytopenia and bone marrow suppression; however, peripheral neuropathy, optic neuritis, and lactic acidosis have been observed with prolonged use due to mitochondrial toxicity. Emergence of resistance has occurred during therapy with either quinupristin/dalfopristin or linezolid.

Pneumococcal Pneumonia

Essentials of Diagnosis

- Productive cough, fever, rigors, dyspnea, early pleuritic chest pain.
- Consolidating lobar pneumonia on chest radiograph.
- Gram-positive diplococci on Gram stain of sputum.

General Considerations

The pneumococcus is the most common cause of community-acquired pyogenic bacterial pneumonia. Alcoholism, asthma, HIV infection, sickle cell disease, splenectomy, and hematologic disorders are predisposing factors. The mortality rate remains high in the setting of advanced age, multilobar disease, severe hypoxemia, extrapulmonary complications, and bacteremia.

Clinical Findings

Symptoms and Signs

Presenting symptoms and signs include high fever, productive cough, occasionally hemoptysis, and pleuritic chest pain. Rigors occur within the first few hours of infection but are uncommon thereafter. Bronchial breath sounds are an early sign.

Laboratory Findings

Pneumococcal pneumonia classically is a lobar pneumonia with radiographic findings of consolidation and occasionally effusion. However, differentiating it from other pneumonias is not possible radiographically or clinically because of significant overlap in presentations. Diagnosis requires isolation of the organism in culture, although the Gram stain appearance of sputum can be suggestive. Sputum and blood cultures, positive in 60% and 25% of cases of pneumococcal pneumonia, respectively, should be obtained prior to initiation of antimicrobial therapy in patients who are admitted to the hospital. A good-quality sputum sample (less than 10 epithelial cells and more than 25 polymorphonuclear leukocytes per high-power field) shows gram-positive diplococci in 80–90% of cases. A rapid urinary antigen test for *S pneumoniae,* with sensitivity of 70–80% and specificity greater than 95%, can assist with early diagnosis.

Complications

Parapneumonic (sympathetic) effusion is common and may cause recurrence or persistence of fever. These sterile fluid accumulations need no specific therapy. Empyema occurs in 5% or less of cases and is differentiated from sympathetic effusion by the presence of organisms on Gram-stained fluid or positive pleural fluid cultures.

Pneumococcal pericarditis is a rare complication that can cause tamponade. Pneumococcal arthritis also is uncommon. Pneumococcal endocarditis usually involves the aortic valve and often occurs in association with meningitis and pneumonia (sometimes referred to as Austrian or Osler triad). Early heart failure and multiple embolic events are typical.

Treatment

Specific Measures

Initial antimicrobial therapy for pneumonia is empiric (see Chapter 9: Pulmonary Disorders for specific recommendations) pending isolation and identification of the causative agent. Once the pneumonia is determined to be caused by *Streptococcus pneumoniae* , any of several antimicrobial agents may be used depending on the clinical setting, community patterns of penicillin resistance, and susceptibility of the particular isolate.

Uncomplicated pneumococcal pneumonia (ie, arterial PO_2 > 60 mm Hg, no coexisting medical problems, and single-lobe disease without signs of extrapulmonary infection) caused by penicillin-susceptible strains of pneumococcus may be treated on an outpatient basis with amoxicillin, 750 mg orally twice daily for 7–10 days. For penicillin-allergic patients, alternatives are azithromycin, one 500-mg dose orally on the first day and 250 mg for the next 4 days; clarithromycin, 500 mg orally twice daily for 10 days; doxycycline, 100 mg orally twice daily for 10 days; levofloxacin, 750 mg orally for 5 days; or moxifloxacin, 400 mg orally for 7–14 days. Patients should be monitored for clinical response (eg, less cough, defervescence within 2–3 days) because pneumococci have become increasingly resistant to penicillin and the second-line agents.

Parenteral therapy is generally recommended for the hospitalized patient at least until there has been clinical improvement. Aqueous penicillin G, 2 million units intravenously every 4 hours, or ceftriaxone, 1 g intravenously every 24 hours, is effective for strains that are not highly penicillin-resistant (ie, strains for which the minimum inhibitory concentration [MIC] of penicillin is 1 mcg/mL). For serious penicillin allergy or infection caused by a highly penicillin-resistant strain, vancomycin, 1 g intravenously every 12 hours, is effective. Alternatively, a fluoroquinolone (eg, levofloxacin, 500 mg, or a comparable dose of any one of several newer fluoroquinolones now on the market, orally or intravenously) can be used. The total duration of therapy is not well defined, but 10–14 days is standard.

Treatment of Complications

Pleural effusions developing after initiation of antimicrobial therapy usually are sterile, and thoracentesis need not be performed if the patient is otherwise improving. Thoracentesis is indicated for an effusion present prior to initiation of therapy and in the patient who has not responded to antibiotics after 3–4 days. Chest tube drainage may be required if pneumococci are identified by culture or Gram stain, especially if aspiration of the fluid is difficult.

Echocardiography should be done if pericardial effusion is suspected. Patients with pericardial effusion who are responding to therapy and have no signs of tamponade may be monitored and treated with indomethacin, 50 mg orally three times daily, for pain. In patients with increasing effusion, unsatisfactory clinical response, or evidence of tamponade, pericardiocentesis will determine whether the pericardial space is infected. Infected fluid must be drained either percutaneously (by tube placement or needle aspiration), by placement of a pericardial window, or by pericardiectomy. Pericardiectomy eventually may be required to prevent or treat constrictive pericarditis, a common sequela of bacterial pericarditis.

Endocarditis should be treated for 4 weeks with 3–4 million units of penicillin G every 4 hours intravenously; ceftriaxone, 2 g once daily intravenously; or vancomycin, 15 mg/kg every 12 hours intravenously. Mild heart failure may respond to medical therapy, but moderate to severe heart failure is an indication for prosthetic valve implantation, as are systemic emboli or large friable vegetations as determined by echocardiography.

Penicillin-Resistant Pneumococci

Susceptibility breakpoints defining penicillin-resistant pneumococci for isolates causing pneumonia were revised in 2008. Resistance breakpoints for parenterally administered penicillin and high-dose oral amoxicillin (2 g twice daily) are as follows: susceptible, penicillin MIC 2 mcg/mL; intermediate, MIC = 4 mcg/mL; resistant, MIC 8 mcg/mL. This change reflected results from studies demonstrating equivalent cure rates when high doses of parenteral penicillin were used for treatment of pneumococcal pneumonia due to isolates with penicillin MIC 2 mcg/mL. Note, however, that these new breakpoints do not apply to orally administered penicillin, which are the same as for use of penicillin in treatment of meningitis (see below). In cases of pneumococcal pneumonia where the isolate has a penicillin MIC > 2 mcg/mL, cephalosporin cross-resistance is common, and a non– -lactam antimicrobial, such as vancomycin, 1 g intravenously every 12 hours or a fluoroquinolone with enhanced gram-positive activity (eg, levofloxacin, 750 mg intravenously or orally once daily or moxifloxacin, 400 mg intravenously or orally once daily), is recommended. Penicillin-resistant strains of pneumococci may be resistant to macrolides, trimethoprim-sulfamethoxazole, and chloramphenicol, and susceptibility must be documented prior to their use. All blood and cerebrospinal fluid isolates should still be tested for resistance to penicillin. There has been no change to the penicillin susceptibility breakpoint for pneumococcal isolates causing meningitis, nor any change in treatment recommendations (see below).

analysis. Clin Infect Dis. 2006 Mar 15;42(6):788–97. [PMID: 16477555]

Pneumococcal Meningitis

Essentials of Diagnosis

- Fever, headache, altered mental status.
- Meningismus.
- Gram-positive diplococci on Gram stain of cerebrospinal fluid.

General Considerations

S pneumoniae is the most common cause of meningitis in adults. Head trauma, with cerebrospinal fluid leaks, sinusitis, and pneumonia may precede it.

Clinical Findings

Symptoms and Signs

The onset is rapid, with fever, headache, meningismus, and altered mentation. Pneumonia may be present. Compared with meningitis caused by the meningococcus, pneumococcal meningitis lacks a rash, and focal neurologic deficits, cranial nerve palsies, and obtundation are more prominent features.

Laboratory Findings

The cerebrospinal fluid typically has more than 1000 white blood cells per microliter, over 60% of which are polymorphonuclear leukocytes; the glucose concentration is less than 40 mg/dL, or less than 50% of the simultaneous serum concentration; and the protein usually exceeds 150 mg/dL. Not all cases of meningitis will have these typical findings, and alterations in cerebrospinal fluid cell counts and chemistries may be surprisingly minimal, overlapping with those of aseptic meningitis.

Gram stain of cerebrospinal fluid shows gram-positive cocci in 80–90% of cases, and in untreated cases blood or cerebrospinal fluid cultures are almost always positive.

Treatment

Antibiotics should be given as soon as the diagnosis is suspected. If lumbar puncture must be delayed (eg, while awaiting results of an imaging study to exclude a mass lesion), the patient should be treated empirically for presumed meningitis with intravenous ceftriaxone, 2 g, plus vancomycin, 15 mg/kg, plus dexamethasone, 0.15 mg/kg administered concomitantly after blood cultures (positive in 50% of cases) have been obtained. Once susceptibility to penicillin has been confirmed, penicillin, 24 million units intravenously daily in six divided doses, or ceftriaxone, 2 g every 12 hours intravenously, is continued for 10–14 days in documented cases.

The best therapy for penicillin-resistant strains is not known. Penicillin-resistant strains (MIC > 0.06 mcg/mL) are often cross-resistant to the third-generation cephalosporins as well as other antibiotics. Susceptibility testing is essential to proper management of this infection. If the MIC of ceftriaxone or cefotaxime is 0.5 mcg/mL, single-drug therapy with either of these cephalosporins is likely to be effective; when the MIC is 1 mcg/mL, treatment with a combination of ceftriaxone, 2 g intravenously every 12 hours, plus vancomycin, 30 mg/kg/d intravenously in two or three divided doses, is recommended. If a patient with a penicillin-resistant organism is slow to respond clinically, repeat lumbar puncture may be indicated to assess bacteriologic response.

Dexamethasone administered with antibiotic to adults has been associated with a 60% reduction in mortality and a 50% reduction in unfavorable outcomes, primarily in patients with pneumococcal meningitis. It is recommended that adults with acute bacterial meningitis be given 10 mg of dexamethasone intravenously immediately prior to or concomitantly with the first dose of appropriate antibiotic and continued in those with pneumococcal disease every 6 hours thereafter for a total of 4 days. Patients with pneumococcal meningitis and AIDS who do not have access to resources may not benefit from dexamethasone. The effect of dexamethasone on outcome of meningitis caused by penicillin-resistant organisms is not known.

Skin & Soft Tissue Infections

Essentials of Diagnosis

- Localized erythema with induration and purulent drainage.
- Abscess formation.
- Folliculitis commonly observed.
- Gram stain of pus with gram-positive cocci in clusters; cultures usually positive.

General Considerations

Approximately one-quarter of people are asymptomatic nasal carriers of *S aureus*, which is spread by direct contact. Carriage often precedes infection, which occurs as a consequence of disruption of the cutaneous barrier or impairment of host defenses. *S aureus* tends to cause more localized skin infections than streptococci, and abscess formation is common. The prevalence of methicillin-resistant strains in community settings is increasing, and these strains have been associated with recurrent and severe skin and soft tissue infections, including necrotizing fasciitis.

Clinical Findings

Symptoms and Signs

S aureus skin infections may begin around one or more hair follicles, causing folliculitis; may become localized to form boils (or furuncles); or may spread to adjacent skin and deeper subcutaneous tissue (ie, a carbuncle) (Plate 100). Deep abscesses involving muscle or fascia may occur, often in association with a deep wound or other inoculation or injection. Necrotizing fasciitis, a rare form of *S aureus* skin and soft tissues infection, has been reported with community strains of methicillin-resistant *S aureus*.

Plate 100
Methicillin-resistant *Staphylococus aureus* (MRSA) abscess of the neck (courtesy of Edward Wright, MD;

Used, with permission, from Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H, Tysinger J. *The Color Atlas of Family Medicine*. McGraw-Hill, 2009.)

Laboratory Findings

Cultures of the wound or abscess material will almost always yield the organism. In patients with systemic signs of infection, blood cultures should be obtained because of potential endocarditis, osteomyelitis, or metastatic seeding of other sites. Patients who are bacteremic should have blood cultures taken early during therapy to exclude persistent bacteremia, an indicator of severe or complicated infection.

Treatment

Proper drainage of abscess fluid or other focal infections is the mainstay of therapy. Incision and drainage alone may be sufficient for cutaneous abscess. For uncomplicated skin infections, oral antimicrobial therapy is satisfactory. Before the emergence of community methicillin-resistant strains of *S aureus*, an oral penicillinase-resistant penicillin or cephalosporin, such as dicloxacillin or cephalexin, 500 mg four times a day for 7–10 days, was the drug of choice for empiric therapy. However, increasing prevalence of methicillin-resistant strains of *S aureus* among community isolates may necessitate use of other oral agents to which the isolate is susceptible in vitro, such as clindamycin, 300 mg three times daily; doxycycline or minocycline, 100 mg twice daily; or trimethoprim-sulfamethoxazole, given in two divided doses based on 5–10 mg/kg/d of the trimethoprim component. Unfortunately, the efficacy of these agents is not well defined and not evidence based. Because of the high prevalence of macrolide resistance among *S aureus* strains, these agents should not be used unless susceptibility is documented.

For more complicated infections with extensive cutaneous or deep tissue involvement or fever, parenteral therapy is indicated initially. A penicillinase-resistant penicillin such as nafcillin or oxacillin in a dosage of 1.5 g every 6 hours intravenously or cefazolin 1 g intravenously or intramuscularly is preferred for infections caused by methicillin-susceptible isolates. In patients with a serious allergy to -lactam antibiotics or if the strain is methicillin-resistant, vancomycin, 1 g intravenously every 12 hours, is a drug of choice. If the local prevalence of methicillin-resistance is high (eg, 10% or more), and particularly if the patient is seriously ill, vancomycin is indicated empirically pending strain isolation and determination of susceptibility.

Linezolid is FDA-approved for treatment of skin and skin-structure infections as well as hospital-acquired pneumonia caused by methicillin-resistant strains of *S* *aureus* and clinically is as effective as vancomycin. The dose is 600 mg orally (bioavailability of 100%) or intravenously twice a day for 10–14 days. Its considerable cost makes it an unattractive choice for most routine outpatient infections, and its safety in treatment courses lasting longer than 2–3 weeks is not well characterized; nevertheless, it is the only proven effective oral alternative to parenteral vancomycin. Daptomycin, 4 mg/kg once daily (or every other day in the patient with creatinine clearance < 30 mL/min) intravenously for 7–14 days, is also an option for treatment of complicated skin and skin structure infections. Tigecycline, a glycylcycline class antimicrobial, has been approved by the FDA for treatment of complicated skin and skin structure infections due to methicillin-resistant strains of *S aureus* at a dose of 100 mg intravenously once followed by 50 mg intravenously twice a day for 10–14 days.

caused by community-acquired methicillin-resistant *Staphylococcus aureus*. Clin Infect Dis. 2008 Jun 1;46(Suppl 5):S368–77. [PMID: 18462092]

Osteomyelitis

S aureus causes approximately 60% of all cases of osteomyelitis. Osteomyelitis may be caused by direct inoculation, eg, from an open fracture or as a result of surgery; by extension from a contiguous focus of infection or open wound; or by hematogenous spread. Long bones and vertebrae are the usual sites. Epidural abscess is a common complication of vertebral osteomyelitis and should be suspected if fever and severe back or neck pain are accompanied by radicular pain or symptoms or signs indicative of spinal cord compression (eg, incontinence, extremity weakness, pathologic reflexes).

Clinical Findings

Symptoms and Signs

The infection may be acute, with abrupt development of local symptoms and systemic toxicity, or indolent, with insidious onset of vague pain over the site of infection, progressing to local tenderness. Fever is absent in one-third or more of cases. Abscess formation is a late and unusual manifestation. Draining sinus tracts occur in chronic infections or infections of foreign body implants.

Laboratory Findings

The diagnosis is established by isolation of *S aureus* from the blood, bone, or a contiguous focus of a patient with signs and symptoms of focal bone infection. Blood culture will be positive in approximately 60% of untreated cases. Bone biopsy and culture are indicated if blood cultures are sterile.

Imaging

Bone scan and gallium scan, each with a sensitivity of approximately 95% and a specificity of 60–70%, are useful in identifying or confirming the site of bone infection. Plain bone films early in the course of infection are often normal but will become abnormal in most cases even with effective therapy. Spinal infection (unlike malignancy) traverses the disk space to involve the contiguous vertebral body. CT is more sensitive than plain films and helps localize associated abscesses. MRI is slightly less sensitive than bone scan but has a specificity of 90%. It is indicated when epidural abscess is suspected in association with vertebral osteomyelitis.

Treatment

Prolonged therapy is required to cure staphylococcal osteomyelitis. Durations of 4–6 weeks or longer are recommended. In cases of staphylococcal osteomyelitis with associated epidural abscess and spinal cord compression, other abscesses (psoas, paraspinal) or extensive disease, surgical treatment is often indicated. Although oral regimens can be effective, parenteral therapy is preferred, particularly during the acute phase of the infection for patients with systemic toxicity. Nafcillin or oxacillin, 9–12 g/d in six divided doses, is the drug of choice for infection with methicillin-sensitive isolates. Cefazolin, 2 g every 6–8 hours, also is effective. Patients with infections due to methicillin-resistant strains of *S aureus* or who have severe penicillin allergies should be treated with vancomycin, 30 mg/kg/d intravenously divided in two or three doses. Doses should be adjusted to achieve a vancomycin trough of 15-20 mcg/mL. Oral step-down therapy to a rifampin combination regimen appears to be as effective as parenterally administered regimens. The role of newer agents, daptomycin or linezolid, remains to be defined.

Daver NG et al. Oral step-down therapy is comparable to intravenous therapy for *Staphylococcus aureus* osteomyelitis. J Infect. 2007 Jun;54(60):539–44. [PMID: 17198732]

Lamp KC et al. Clinical experience with daptomycin for the treatment of patients with osteomyelitis. Am J Med. 2007 Oct;120(10 Suppl 1):S13–20. [PMID: 17904946]

Staphylococcal Bacteremia

S aureus readily invades the bloodstream and infects sites distant from the primary site of infection, which may be relatively minor or even inapparent. Whenever *S aureus* is recovered from blood cultures, the possibility of endocarditis, osteomyelitis, or other metastatic deep infection must be considered. Bacteremia that persists for more than 48 to 96 hours after initiation of therapy is strongly predictive of worse outcome and complicated infection. The appropriate duration of therapy for uncomplicated bacteremia arising from a removable source (eg, intravenous device) or drainable focus (eg, skin abscess) has not been well defined, but a 10- to 14-day course of therapy appears to be the minimum. However, 5% or more of patients may relapse, usually with endocarditis or osteomyelitis, even if treated for 2 weeks.

Nafcillin or oxacillin, 2 g intravenously every 4 hours or cefazolin, 2 g every 8 hours is recommended for uncomplicated methicillin-susceptible *S aureus* bacteremia. Vancomycin, 30 mg/kg/d intravenously in two or three divided doses, as definitive therapy should be reserved for patients with serious penicillin allergy or with infections caused by methicillin-resistant strains because it is less active than -lactam antibiotics and treatment failures are more common than with -lactams. Maintaining a vancomycin trough concentration of 15–20 mcg/mL may improve outcomes and is recommended. Transesophageal echocardiography (TEE) is a sensitive and cost-effective method for excluding underlying endocarditis. It is considered for patients for whom the pretest probability of endocarditis is 5% or higher—and for all patients with unexplained *S aureus* bacteremia.

Vancomycin treatment failures are relatively common, particularly for complicated bacteremia, in foreign body infection, or when the MIC of the isolate is 2 mcg/mL. Consultation should be sought with an infectious diseases specialist when vancomycin treatment failure is encountered. Daptomycin, 6 mg/kg once daily, is approved by the FDA for treatment of *S aureus* bacteremia and is an alternative to vancomycin, especially if a -lactam cannot be used or if the patient is not responding to vancomycin. Cases of vancomycin treatment failures in which the staphylococcal isolate exhibits a vancomycin MIC 4 mcg/mL should be reported to the Centers for Disease Control and Prevention (CDC) to help track this potentially serious and emerging problem of vancomycin resistance.

Empiric therapy of suspected staphylococcal infection, whether of community or hospital onset, depends on the severity of the infection and the likelihood that it is caused by methicillin-resistant strains. If the prevalence exceeds 5–10% for more seriously ill patients, initial therapy should include vancomycin, 30 mg/kg/d intravenously divided in two or three doses, until results of susceptibility tests are known. Resistance to vancomycin fortunately remains rare and should not affect the choice of empiric therapy.

Toxic Shock Syndrome

S aureus produces toxins that cause three important entities: "scalded skin syndrome" in children, toxic shock syndrome in adults, and enterotoxin food poisoning. Toxic shock syndrome is characterized by abrupt onset of high fever, vomiting, and watery diarrhea. Sore throat, myalgias, and headache are common. Hypotension with kidney and heart failure is associated with a poor outcome. A diffuse macular erythematous rash (Plate 101) and nonpurulent conjunctivitis are common, and desquamation, especially of palms and soles, is typical during recovery. Fatality rates may be as high as 15%. Although originally associated with tampon use, any focus (eg, nasopharynx, bone, vagina, rectum, abscess, or wound) harboring a toxin-producing *S aureus* strain can cause toxic shock syndrome and nonmenstrual cases of toxic shock syndrome are common. Classically, blood cultures are negative because symptoms are due to the effects of the toxin and not systemic infection.

Plate 101.

Morbiliform rash in toxic shock syndrome caused by *Staphylococcus aureus*. (Public Health Image Library, CDC.)

Important aspects of treatment include rapid rehydration, antistaphylococcal drugs, management of kidney or heart failure, and addressing sources of toxin, eg, removal of tampon or drainage of abscess.

Infections Caused by Coagulase-Negative Staphylococci

Coagulase-negative staphylococci are an important cause of infections of intravascular and prosthetic devices and of wound infection following cardiothoracic surgery. These organisms infrequently cause infections such as osteomyelitis and endocarditis in the absence of a prosthesis, but rates may be increasing. Most human infections are caused by *Staphylococcus epidermidis, Staphylococcus haemolyticus, Staphylococcus hominis, Staphylococcus warnerii, Staphylococcus saprophyticus, Staphylococcus saccharolyticus,* and *Staphylococcus cohnii.* These common hospital-acquired pathogens are less virulent than *S aureus*, and infections caused by them tend to be more indolent.

Because coagulase-negative staphylococci are normal inhabitants of human skin, it is difficult to distinguish infection from contamination, the latter perhaps accounting for three-fourths of blood culture isolates. Infection is more likely if the patient has a foreign body (eg, sternal wires, prosthetic joint, prosthetic cardiac valve, pacemaker, intracranial pressure monitor, cerebrospinal fluid shunt, peritoneal dialysis catheter) or an intravascular device in place. Purulent or serosanguineous drainage, erythema, pain, or tenderness at the site of the foreign body or device suggests infection. Instability and pain are signs of prosthetic joint infection. Fever, a new murmur, instability of the prosthesis, or signs of systemic embolization are evidence of prosthetic valve endocarditis. Immunosuppression and recent antimicrobial therapy are risk factors.

Infection is also more likely if the same strain is consistently isolated from two or more blood cultures (particularly if samples were obtained at different times) and from the foreign body site. Contamination is more likely when a single blood culture is positive or if more than one strain is isolated from blood cultures. The antimicrobial susceptibility pattern and speciation are used to determine whether one or more strains have been isolated. More sophisticated typing methods, eg, pulse-field gel electrophoresis of restriction enzyme digested chromosomal DNA, may be required to identify distinct strains.

Whenever possible, the intravascular device or foreign body suspected of being infected by coagulase-negative staphylococci should be removed. However, removal and replacement of some devices (eg, prosthetic joint, prosthetic valve, cerebrospinal fluid shunt) can be a difficult or risky procedure, and it may sometimes be preferable to treat with antibiotics alone with the understanding that the probability of cure is reduced and that surgical management may eventually be necessary.

Coagulase-negative staphylococci are commonly resistant to -lactams and multiple other antibiotics. For patients with normal kidney function, vancomycin, 1 g intravenously every 12 hours, is the treatment of choice for suspected or confirmed infection caused by these organisms until susceptibility to penicillinase-resistant penicillins or other agents has been confirmed. Duration of therapy has not been established for relatively uncomplicated infections, such as those secondary to intravenous devices, which may be eliminated by simply removing the infected device. Infection involving bone or a prosthetic valve should be treated for 6 weeks. A combination regimen of vancomycin plus rifampin, 300 mg orally twice daily, and gentamicin, 1 mg/kg intravenously every 8 hours, is recommended for treatment of prosthetic valve endocarditis caused by methicillin-resistant strains.

Chu VH et al. Emergence of coagulase-negative staphylococci as a cause of native valve endocarditis. Clin Infect Dis. 2008 Jan 15;46(2):232–42. [PMID: 18171255]

Clostridial Myonecrosis (Gas Gangrene)

Essentials of Diagnosis

- Sudden onset of pain and edema in an area of wound contamination.
- Prostration and systemic toxicity.
- Brown to blood-tinged watery exudate, with skin discoloration of surrounding area.
- Gas in the tissue by palpation or radiograph.
- Gram-positive rods in culture or smear of exudate.

General Considerations

Gas gangrene or clostridial myonecrosis is produced by any one of several clostridia (*Clostridium perfringens, Clostridium ramosum*, *Clostridium bifermentans, Clostridium histolyticum*, *Clostridium novyi*, etc). Trauma and injection drug use are common predisposing conditions. Toxins produced into devitalized tissues under anaerobic conditions result in shock, hemolysis, and myonecrosis.

Clinical Findings

Symptoms and Signs

The onset is usually sudden, with rapidly increasing pain in the affected area, hypotension, and tachycardia. Fever is present but is not proportionate to the severity of the infection. In the last stages of the disease, severe prostration, stupor, delirium, and coma occur.

The wound becomes swollen, and the surrounding skin is pale. There is a foul-smelling brown, blood-tinged serous discharge. As the disease advances, the surrounding tissue changes from pale to dusky and finally becomes deeply discolored, with coalescent, red, fluid-filled vesicles. Gas may be palpable in the tissues.

Laboratory Findings

Gas gangrene is a clinical diagnosis, and empiric therapy is indicated if the diagnosis is suspected. Radiographic studies may show gas within the soft tissues, but this finding is not specific. The smear shows absence of neutrophils and the presence of gram-positive rods. Anaerobic culture confirms the diagnosis.

Differential Diagnosis

Other bacteria can produce gas in infected tissue, eg, enteric gram-negative organisms, or anaerobes.

Treatment

Penicillin, 2 million units every 3 hours intravenously, is effective. Other agents (eg, tetracycline, clindamycin, metronidazole, chloramphenicol, cefoxitin) are active against *Clostridium* species in vitro and probably in vivo as well. Adequate surgical debridement and exposure of infected areas are essential, with radical surgical excision often necessary. Hyperbaric oxygen therapy has been used empirically but must be used in conjunction with administration of an appropriate antibiotic and surgical debridement.

Clostridium sordellii Toxic Shock Syndrome

Essentials of Diagnosis

- Sudden onset after medical abortion.
- Abdominal pain.

- Absence of fever.
- Tachycardia, severe hypotension, capillary leak syndrome with edema.
- Profound leukocytosis, hemoconcentration.

General Considerations & Clinical Findings

C sordellii is a rare cause of endometritis and toxic shock syndrome following childbirth. Four cases, all fatal, of uterine infection following medically induced abortion with mifepristone were reported in 2005. Onset of illness was within 4–5 days of ingestion of mifepristone and the clinical course fulminant. Infection appeared to be limited to the uterus, which showed necrosis, edema, hemorrhage, and acute inflammatory changes.

Treatment

Early recognition, aggressive resuscitation from shock, immediate surgical debridement with hysterectomy, and administration of an antimicrobial that is active against *C sordellii* are essential to survival. Based on in vitro susceptibility data, any of several agents should be active, including penicillin, ampicillin, a macrolide, clindamycin, a tetracycline, or metronidazole. Whether a protein synthesis inhibitor to block further toxin production offers any advantage over a -lactam is unknown.

Cohen AL et al. Toxic shock associated with *Clostridium*

sordellii and *Clostridium perfringens* after medical and spontaneous abortion. Obstet Gynecol. 2007 Nov;110(5):1027–33. [PMID: 17978116]

Tetanus

Essentials of Diagnosis

- History of wound and possible contamination.
- Jaw stiffness followed by spasms of jaw muscles (trismus).
- Stiffness of the neck and other muscles, dysphagia, irritability, hyperreflexia.
- Finally, painful convulsions precipitated by minimal stimuli.

General Considerations

Tetanus is caused by the neurotoxin tetanospasmin, elaborated by *Clostridium tetani*. Spores of this organism are ubiquitous in soil and may germinate when introduced into a wound. The vegetative bacteria produce tetanospasmin, a zinc metalloprotease that cleaves synaptobrevin, a protein essential for neurotransmitter release. Tetanospasmin interferes with neurotransmission at spinal synapses of inhibitory neurons. As a result, minor stimuli result in uncontrolled spasms, and reflexes are exaggerated. The incubation period is 5 days to 15 weeks, with the average being 8–12 days.

Most cases occur in unvaccinated individuals. Persons at risk are the elderly, migrant workers, newborns, and injection drug users. While puncture wounds are particularly prone to causing tetanus, any wound, including bites or decubiti, may become colonized and infected by *C tetani*.

Clinical Findings

Symptoms and Signs

The first symptom may be pain and tingling at the site of inoculation, followed by spasticity of the muscles nearby. Stiffness of the jaw, neck stiffness, dysphagia, and irritability are other early signs. Hyperreflexia develops later, with spasms of the jaw muscles (trismus) or facial muscles and rigidity and spasm of the muscles of the abdomen, neck, and back. Painful tonic convulsions precipitated by minor stimuli are common. Spasms of the glottis and respiratory muscles may cause acute asphyxia. The patient is awake and alert throughout the illness. The sensory examination is normal. The temperature is normal or only slightly elevated.

Laboratory Findings

The diagnosis of tetanus is made clinically.

Differential Diagnosis

Tetanus must be differentiated from various acute central nervous system infections such as meningitis. Trismus may occasionally develop with the use of phenothiazines. Strychnine poisoning should also be considered.

Complications

Airway obstruction is common. Urinary retention and constipation may result from spasm of the sphincters. Respiratory arrest and cardiac failure are late, life-threatening events.

Prevention

Tetanus is completely preventable by active immunization. For primary immunization of adults, Td (tetanus and diphtheria toxoids vaccine) is administered as two doses 4–6 weeks apart, with a third dose 6–12 months later. For one of the doses, Tdap (tetanus toxoid, reduced dose diphtheria toxoid, acellular pertussis vaccine) should be substituted for Td. Booster doses are given every 10 years or at the time of major injury if it occurs more than 5 years after a dose. A single dose of Tdap is preferred to Td for wound prophylaxis if the patient has not been previously vaccinated with Tdap.

Passive immunization should be used in nonimmunized individuals and those whose immunization status is uncertain whenever a wound is contaminated or likely to have devitalized tissue. Tetanus immune globulin, 250 units, is given intramuscularly. Active immunization with tetanus toxoid is started concurrently. Table 33–1 provides a guide to prophylactic management.

Table 33–1. Guide to tetanus prophylaxis in wound management.

History of Absorbed Tetanus Toxoid	**Clean, Minor Wounds**		**All Other Wounds[1]**	
	Td[2]	**TIG[3]**	**Td[2]**	**TIG[3]**
Unknown or < 3 doses	Yes	No	Yes	Yes
3 or more doses	No[4]	No	No[5]	No

[1] Such as, but not limited to, wounds contaminated with dirt, feces, soil, saliva, etc; puncture wounds; avulsions; and wounds resulting from missiles, crushing, burns, and frostbite.

[2] Td indicates tetanus toxoid and diphtheria toxoid, adult form. Tdap indicates tetanous toxoid, reduced diphtheria toxoid, and acellular pertussis vaccine, which may be substituted as a single dose for Td. Unvaccinated individuals should receive a complete series of three

doses, one of which is Tdap.

[3] Human tetanus immune globulin, 250 units intramuscularly.

[4] Yes if more than 10 years have elapsed since last dose.

[5] Yes if more than 5 years have elapsed since last dose. (More frequent boosters are not needed and can enhance side effects.) Tdap has been safely administered within 2 years of Td vaccination, although local reactions to the vaccine may be increased.

Treatment

Specific Measures

Human tetanus immune globulin, 500 units, should be administered intramuscularly within the first 24 hours of presentation. Whether intrathecal administration has any additional benefit is controversial. An unblinded, randomized trial comparing intramuscular tetanus immune globulin to intramuscular plus intrathecal tetanus immune globulin found more rapid resolution of spasms, fewer days of ventilatory support, and a shorter hospital stay in the intrathecal group. However, the exact immunoglobulin preparation that was used was not specified and the total dose was 4000 units. Tetanus does not produce natural immunity, and a full course of immunization with tetanus toxoid should be administered once the patient has recovered.

General Measures

Minimal stimuli can provoke spasms, so the patient should be placed at bed rest and monitored under the quietest conditions possible. Sedation, paralysis with curare-like agents, and mechanical ventilation are often necessary to control tetanic spasms. Penicillin, 20 million units intravenously daily, is given to all patients—even those with mild illness—to eradicate toxin-producing organisms.

Prognosis

High mortality rates are associated with a short incubation period, early onset of convulsions, and delay in treatment. Contaminated lesions about the head and face are more dangerous than wounds on other parts of the body.

Zimmerman RK et al. Routine vaccines across the life span, 2007. J Fam Pract. 2007 Feb;56(2 Suppl Vaccines):S18–37, C1–3. [PMID: 17270108]

Botulism

Essentials of Diagnosis

- History of recent ingestion of home-canned or smoked foods or of injection drug use and demonstration of toxin in serum or food.
- Sudden onset of diplopia, dry mouth, dysphagia, dysphonia, and muscle weakness progressing to respiratory paralysis.
- Pupils are fixed and dilated in most cases.

General Considerations

Botulism is a paralytic disease caused by botulinum toxin, which is produced by *Clostridium botulinum*, a ubiquitous, strictly anaerobic, spore-forming bacillus found in soil. Four toxin types—A, B, E, and F—cause human disease. Botulinum toxin is a zinc metalloprotease that cleaves a specific component of the synaptic vesicle membrane docking and fusion complex at the neuromuscular junction blocking release of the neurotransmitter acetylcholine. Botulinum toxin is extremely potent and is classified by the CDC as a high-priority agent because of its potential for use as an agent of bioterrorism. Naturally occurring botulism occurs in one of three forms: food-borne botulism, infant botulism, or wound botulism. Food-borne botulism is caused by ingestion of preformed toxin present in canned, smoked, or vacuum-packed foods such as home-canned vegetables, smoked meats, and vacuum-packed fish. Commercial foods have also been associated with outbreaks of botulism. Infant botulism (associated with ingestion of honey) and wound botulism (which typically occurs in association with injection drug use) result from organisms present in the gut or wound that elaborate toxin in vivo.

Clinical Findings

Symptoms and Signs

Twelve to 36 hours after ingestion of the toxin, visual disturbances appear, particularly diplopia and loss of accommodation. Ptosis, cranial nerve palsies with impairment of extraocular muscles, and fixed dilated pupils are characteristic signs. The sensory examination is normal. Other symptoms are dry mouth, dysphagia, and dysphonia. Nausea and vomiting may be present, particularly with type E toxin. The sensorium remains clear and the temperature normal. Paralysis progressing to respiratory failure and death may occur unless mechanical assistance is provided.

Laboratory Findings

Toxin in patients' serum and in suspected foods can be demonstrated by mouse inoculation and identified with specific antiserum.

Differential Diagnosis

Because the clinical presentation of botulism is so distinctive and the differential diagnosis limited, botulism once considered is not easily confused with other diseases. Cranial nerve involvement may be seen with vertebrobasilar insufficiency, the C. Miller Fisher variant of Guillain-Barré syndrome, myasthenia gravis, or any basilar meningitis (infectious or carcinomatous). Intestinal obstruction or other types of food poisoning are considered when nausea and vomiting are present.

Treatment

If botulism is suspected, the practitioner should contact the state health authorities or the CDC for advice and help with procurement of botulinus antitoxin and for assistance in obtaining assays for toxin in serum, stool, or food. Skin testing is recommended to exclude hypersensitivity to the antitoxin preparation. Antitoxin should be administered as early as possible, ideally within 24 hours of the onset of symptoms or signs, to arrest progression of disease; its administration should not be delayed for laboratory confirmation of the diagnosis. Respiratory failure is managed with intubation and mechanical ventilation. Parenteral fluids or alimentation should be given while swallowing difficulty persists. The removal of unabsorbed toxin from the gut may be attempted. Any remnants of suspected foods should be assayed for toxin. Persons who might have eaten the suspected food must be located and observed.

Anthrax

Essentials of Diagnosis

- Appropriate epidemiologic setting, eg, exposure to animals or animal hides, or potential exposure resulting from an act of bioterrorism.
- A painless cutaneous black eschar on exposed areas

of the skin, with marked surrounding edema and vesicles.
- Nonspecific flu-like symptoms that rapidly progress to extreme dyspnea and shock in association with mediastinal widening and pleural effusions on chest radiograph.

General Considerations

The death of a Florida photo editor from inhalational anthrax acquired from a letter deliberately contaminated with spores of *Bacillus anthracis* thrust this extremely rare infection into the public awareness. Between September 18 and November 21 of 2001, there were 13 cases of cutaneous anthrax and 11 cases of inhalational anthrax associated with exposure to anthrax spores in contaminated mail.

Naturally occurring anthrax is a disease of sheep, cattle, horses, goats, and swine. *B anthracis* is a gram-positive spore-forming aerobic rod. Spores—not vegetative bacteria—are the infectious form of the organism. These are transmitted to humans from contact with contaminated animals, animal products, or animal hides, or from soil by inoculation of broken skin or mucous membranes; by inhalation of aerosolized spores; or, rarely, by ingestion resulting in cutaneous, inhalational, or gastrointestinal forms of anthrax, respectively. Spores germinate into vegetative bacteria that multiply locally in cutaneous and gastrointestinal anthrax but may also disseminate to cause systemic infection. Inhaled spores are ingested by pulmonary macrophages and carried via lymphatics to regional lymph nodes, where they germinate. The bacteria rapidly multiply within the lymphatics, causing a hemorrhagic lymphadenitis. Invasion of the bloodstream leads to overwhelming sepsis, killing the host. Virulence is determined by two plasmids, pXO1 and pXO2, which encode, respectively, genes for two toxins, lethal toxin and edema toxin, and genes for capsule production. Loss of either plasmid attenuates strain virulence. Edema toxin impairs neutrophil function and probably is responsible for the striking edema present in cutaneous anthrax. Lethal factor provokes a cytokine-mediated shock syndrome. The capsule allows the bacteria to evade host immune defenses.

Clinical Findings

Symptoms and Signs

Cutaneous Anthrax

This occurs within 2 weeks after exposure to spores; there is no latency period for cutaneous disease. The initial lesion is an erythematous papule, often on an exposed area of skin that vesiculates and then ulcerates and undergoes necrosis, ultimately progressing to a purple to black eschar. The eschar typically is painless; pain indicates secondary staphylococcal or streptococcal infection. The surrounding area is edematous and vesicular but not purulent. Regional adenopathy, fever, malaise, headache, and nausea and vomiting may be present. The infection is self-limited in most cases, but hematogenous spread with sepsis or meningitis may occur.

Inhalational Anthrax

Illness occurs in two stages, beginning on average 10 days after exposure, but may begin up to 6 weeks after exposure. Nonspecific viral-like symptoms such as fever, malaise, headache, dyspnea, cough, and congestion of the nose, throat, and larynx are characteristic of the initial stage. Anterior chest pain is an early symptom of mediastinitis. Within hours to a few days, progression to the fulminant stage of infection occurs in which symptoms or signs of overwhelming sepsis predominate. Delirium, obtundation, or findings of meningeal irritation suggest an accompanying hemorrhagic meningitis.

Gastrointestinal Anthrax

This form has not been reported in the United States. Fever, diffuse abdominal pain, rebound abdominal tenderness, vomiting, constipation, and diarrhea occur 2–5 days after ingestion of meat contaminated with anthrax spores. The primary lesion is ulcerative, producing emesis that may be blood-tinged or coffee-grounds and stool that may be blood-tinged or melenic. Bowel perforation can occur. The oropharyngeal form of the disease is characterized by local lymphadenopathy, cervical edema, dysphagia, and upper respiratory tract obstruction.

Laboratory Findings

Laboratory findings are nonspecific. The white blood cell count initially may be normal or modestly elevated, with polymorphonuclear predominance and an increase in early forms. Pleural fluid from patients with inhalational anthrax is typically hemorrhagic with few white cells. Cerebrospinal fluid from meningitis cases is also hemorrhagic. Gram stain of pleural fluid, cerebrospinal fluid, unspun blood, blood culture, or fluid from a cutaneous lesion may show the characteristic boxcar-shaped encapsulated rods in chains.

The diagnosis is established by isolation of the organism from culture of the skin lesion (or fluid expressed from it), blood, or pleural fluid—or cerebrospinal fluid in cases of meningitis. In the absence of prior antimicrobial therapy, cultures are invariably positive. Cultures obtained after initiation of antimicrobial therapy may be negative. If anthrax is suspected on clinical or epidemiologic grounds, immunohistochemical tests (eg, to detect capsular antigen), polymerase chain reaction assays, and serologic tests (useful for documenting past cutaneous infection) are available through the CDC and should be used to establish the diagnosis. Any suspected case of anthrax should be immediately reported to the CDC so that a complete investigation can be conducted.

Imaging

The chest radiograph is the most sensitive test for inhalational disease, being abnormal (though the findings can be subtle) initially in every case of bioterrorism-associated disease. Mediastinal widening due to hemorrhagic lymphadenitis, a hallmark feature of the disease, has been present in 70% of the bioterrorism-related cases. Pleural effusions were present initially or occurred over the course of illness in all cases, and approximately three-fourths had pulmonary infiltrates or signs of consolidation.

Differential Diagnosis

Cutaneous anthrax, despite its characteristic appearance, can be confused with a variety of other also uncommon or rare conditions such as ecthyma gangrenosum, rat-bite fever, ulceroglandular tularemia, plague, glanders, rickettsialpox, orf (parapoxvirus infection), or cutaneous mycobacterial infection. Inhalational anthrax must be differentiated from mediastinitis due to other bacterial causes, fibrous mediastinitis due to histoplasmosis, coccidioidomycosis, atypical or viral pneumonia, silicosis, sarcoidosis, and other causes of mediastinal widening (eg, superior vena cava syndrome or aortic aneurysm or dissection). Gastrointestinal anthrax shares clinical features with a variety of common intra-abdominal disorders, including bowel obstruction, perforated viscus, peritonitis, gastroenteritis, and peptic ulcer disease.

Treatment

Strains of *B anthracis* (including the strain isolated in the bioterrorism cases) are susceptible in vitro to penicillin, amoxicillin, chloramphenicol, clindamycin, imipenem, doxycycline, ciprofloxacin (as well as other fluoroquinolones), macrolides, rifampin, and vancomycin. Susceptibility to cephalosporins is variable. *B anthracis* may express -lactamases that confer resistance to cephalosporins and penicillins. For this reason, penicillin or amoxicillin is no longer recommended for use as a single agent in treatment of disseminated disease. Based on results of animal experiments and because of concern for engineered drug resistance in strains of *B anthracis* used in bioterrorism or weaponized, ciprofloxacin is considered the drug of choice (Table 33–2) for treatment and for prophylaxis following exposure to anthrax spores. Other fluoroquinolones with activity against gram-positive bacteria (eg, levofloxacin, moxifloxacin), are likely to be just as effective as ciprofloxacin. Doxycycline is an alternative first-line agent. Combination therapy with at least one additional agent is recommended for inhalational or disseminated disease and in cutaneous infection involving the face, head, and neck or associated with extensive local edema or systemic signs of infection, eg, fever, tachycardia and elevated white blood cell count. Anecdotally, four of the six survivors of the 2001 inhalational cases were treated with combinations that included both a fluoroquinolone and rifampin. Single-drug therapy is recommended for prophylaxis following exposure to spores.

Table 33–2. Antimicrobial agents for treatment of anthrax or for prophylaxis against anthrax.
First-line agents and recommended doses
Ciprofloxacin, 500 mg twice daily orally or 400 mg every 12 hours intravenously
Doxycycline, 100 mg every 12 hours orally or intravenously
Second-line agents and recommended doses
Amoxicillin, 500 mg three times daily orally
Penicillin G, 2–4 million units every 4 hours intravenously
Alternative agents with in vitro activity and suggested doses

Rifampin, 10 mg/kg/d orally or intravenously
Clindamycin, 450–600 mg every 8 hours orally or intravenously
Clarithromycin, 500 mg orally twice daily
Erythromycin, 500 mg every 6 hours intravenously
Vancomycin, 1 g every 12 hours intravenously
Imipenem, 500 mg every 6 hours intravenously

The required duration of therapy is poorly defined. In naturally occurring disease, treatment for 7–10 days for cutaneous disease and for at least 2 weeks following clinical response for disseminated, inhalational, or gastrointestinal infection have been standard recommendations. Because of concern about relapse from latent spores acquired by inhalation of aerosol in bioterrorism-associated cases, the initial recommendation was treatment for 60 days. In 2001, the CDC offered one of two options for postal workers receiving prophylaxis for exposure to contaminated mail: (1) antibiotics for 100 days (fearing that even with 60 days of treatment late relapses might occur) or (2) vaccination with an investigative agent (three doses administered over a 1-month period) in conjunction with 40 days of antibiotic administration to cover the time required for a protective antibody response to develop. Insufficient information exists to favor one recommendation over the other.

There is also an FDA-approved vaccine for persons at high risk for exposure to anthrax spores. The vaccine is cell-free antigen prepared from an attenuated strain of *B anthracis.* Multiple injections over 18 months and an annual booster dose are required to achieve and maintain protection. Existing supplies have been reserved for vaccination of military personnel.

The prognosis in cutaneous infection is excellent. Death is unlikely if the infection has remained localized, and lesions heal without complications in most cases. The reported mortality rate for gastrointestinal and inhalational infections is up to 85%. The experience with bioterrorism-associated inhalational cases in which six of eleven victims survived suggests a somewhat better outcome with modern supportive care and antibiotics provided that treatment is initiated before the patient has progressed to the fulminant stage of disease. No cases of anthrax have occurred among the several thousand individuals receiving antimicrobial prophylaxis following exposure to spores.

Kyriacou DN et al. Discriminating inhalational anthrax from community-acquired pneumonia using chest radiograph findings and a clinical algorithm. Chest. 2007 Feb;131(2):489–96. [PMID: 17296652]

Diphtheria

Essentials of Diagnosis

- Tenacious gray membrane at portal of entry in pharynx.
- Sore throat, nasal discharge, hoarseness, malaise, fever.
- Myocarditis, neuropathy.
- Culture confirms the diagnosis.

General Considerations

Diphtheria is an acute infection, caused by *Corynebacterium diphtheriae*, that usually attacks the respiratory tract but may involve any mucous membrane or skin wound. The organism is spread chiefly by respiratory secretions. Exotoxin produced by the organism is responsible for myocarditis and neuropathy. This exotoxin inhibits elongation factor, which is required for protein synthesis.

Clinical Findings

Symptoms and Signs

Nasal, laryngeal, pharyngeal, and cutaneous forms of diphtheria occur. Nasal infection produces few symptoms other than a nasal discharge. Laryngeal infection may lead to upper airway and bronchial obstruction. In pharyngeal diphtheria, the most common form, a tenacious gray membrane covers the tonsils and pharynx. Mild sore throat, fever, and malaise are followed by toxemia and prostration.

Myocarditis and neuropathy are the most common and most serious complications. Myocarditis causes cardiac arrhythmias, heart block, and heart failure. The neuropathy usually involves the cranial nerves first, producing diplopia, slurred speech, and difficulty in swallowing.

Laboratory Findings

The diagnosis is made clinically but can be confirmed by culture of the organism.

Differential Diagnosis

Diphtheria must be differentiated from streptococcal pharyngitis, infectious mononucleosis, adenovirus or herpes simplex infection, Vincent angina, pharyngitis due to *Arcanobacterium haemolyticum*, and candidiasis. A presumptive diagnosis of diphtheria should be made on clinical grounds without waiting for laboratory verification, since emergency treatment is needed.

Prevention

Active immunization with diphtheria toxoid is part of routine childhood immunization with appropriate booster injections. The immunization schedule for adults is the same as for tetanus.

Susceptible persons exposed to diphtheria should receive a booster dose of diphtheria toxoid (or a complete series if previously unimmunized), as well as a course of penicillin or erythromycin.

Treatment

Antitoxin, which is prepared from horse serum, must be given in all cases when diphtheria is suspected. For mild early pharyngeal or laryngeal disease, the dose is 20,000–40,000 units; for moderate nasopharyngeal disease, 40,000–60,000 units; for severe, extensive, or late (3 days or more) disease, 80,000–100,000 units. Diphtheria equine antitoxin can be obtained from the CDC.

Removal of membrane by direct laryngoscopy or bronchoscopy may be necessary to prevent or alleviate airway obstruction.

Either penicillin, 250 mg orally four times daily, or erythromycin, 500 mg orally four times daily, for 14 days is effective therapy, although erythromycin is slightly more effective in eliminating the carrier state. Azithromycin or clarithromycin is probably as effective as erythromycin. The patient should be isolated until three consecutive cultures at the completion of therapy have documented elimination of the organism from the oropharynx. Contacts to a case should receive erythromycin, 500 mg orally four times daily for 7 days, to eradicate carriage.

Hitchcock WP. Rationale for use of Tdap booster vaccines for adolescent immunization: overview of efficacy, safety, and clinical use. Clin Pediatr (Phila). 2006 Nov;45(9):785–94. [PMID: 17041165]

Listeriosis

Listeria monocytogenes is a facultative, motile, gram-positive rod that is capable of invading several cell types and causes intracellular infection. Most cases of infection caused by *L monocytogenes* are sporadic, but outbreaks have been traced to eating contaminated food, including unpasteurized dairy products, hot dogs, and delicatessen meats. Five types of infection are recognized:

> (1) **Infection during pregnancy,** usually in the last trimester, is a mild febrile illness without an apparent primary focus. This relatively benign disease for the mother may resolve without specific therapy. However, approximately one in five pregnancies complicated by listeriosis result in spontaneous abortion or stillbirth and surviving infants are at high risk for clinical neonatal listeriosis.
>
> (2) **Granulomatosis infantisepticum** is a neonatal infection acquired in utero, characterized by disseminated abscesses, granulomas, and a high

mortality rate.

(3) **Bacteremia** with or without sepsis syndrome is an infection of neonates or immunocompromised adults. The presentation is of a febrile illness without a recognized source.

(4) **Meningitis** caused by *L monocytogenes* affects infants under 2 months of age as well as older adults, ranking third after the meningococcus and pneumococcus among the common causes of bacterial meningitis. Cerebrospinal fluid shows a *neutrophilic* pleocytosis. Adults with meningitis are often immunocompromised, and cases have been associated with HIV infection and therapy with tumor necrosis factor- (TNF-) inhibitors such as infliximab.

(5) Finally, **focal infections**, including adenitis, brain abscess, endocarditis, osteomyelitis, and arthritis, occur rarely.

Ampicillin, 8–12 g/d intravenously in four to six divided doses (the higher dose for meningitis) is considered the treatment of choice. It penetrates well into cerebrospinal fluid, and clinical response is better than with penicillin, erythromycin, or chloramphenicol. Gentamicin is synergistic with ampicillin against *Listeria* in vitro and in animal models, and the use of combination therapy may be considered during the first few days of treatment to enhance eradication of organisms. Mortality and morbidity rates still are high, and relapses occur, perhaps related to poor intracellular penetration of ampicillin. Trimethoprim-sulfamethoxazole with its excellent intracellular and cerebrospinal fluid penetration may be more efficacious. The dose is 10–20 mg/kg/d intravenously of the trimethoprim component. Therapy should be administered for at least 2–3 weeks. Longer durations—between 3 and 6 weeks—have been recommended for treatment of meningitis, especially in immunocompromised persons.

Bennion JR et al. Decreasing listeriosis mortality in the United States, 1990–2005. Clin Infect Dis. 2008 Oct 1;47(7):867–74. [PMID: 18752441]

Infective Endocarditis

Essentials of Diagnosis

- Fever.
- Preexisting organic heart lesion.
- Positive blood cultures.
- Evidence of vegetation on echocardiography.
- New or changing heart murmur.
- Evidence of systemic emboli.

General Considerations

Endocarditis is a bacterial or fungal infection of the valvular or endocardial surface of the heart. The clinical presentation depends on the infecting organism and the valve or valves that are infected. More virulent organisms—*S aureus* in particular—tend to produce a more rapidly progressive and destructive infection. Endocarditis caused by more virulent organisms often presents as an acute febrile illnesses and is complicated by early embolization, acute valvular regurgitation, and myocardial abscess formation. Viridans strains of streptococci, enterococci, other bacteria, yeasts, and fungi tend to cause a more subacute picture.

Underlying valvular disease, less common than in the past, is present in about 50% of cases. Valvular disease alters blood flow and produces jet effects that disrupt the endothelial surface, providing a nidus for attachment and infection of microorganisms that enter the bloodstream. Predisposing valvular abnormalities include rheumatic involvement of any valve, bicuspid aortic valves, calcific or sclerotic aortic valves, hypertrophic subaortic stenosis, mitral valve prolapse, and a variety of congenital disorders such as ventricular septal defect, tetralogy of Fallot, coarctation of the aorta, or patent ductus arteriosus. Rheumatic disease is no longer the major predisposing factor in developed countries. Regurgitation lesions are more susceptible than stenotic ones.

The initiating event in native valve endocarditis is colonization of the valve by bacteria or yeast that gain access to the bloodstream. Transient bacteremia is common during dental, upper respiratory, urologic, and lower gastrointestinal diagnostic and surgical procedures. It is less common during upper gastrointestinal and gynecologic procedures. Intravascular devices are increasingly implicated as a portal of access of microorganisms into the bloodstream. A large proportion of cases of *S aureus* endocarditis are attributable to healthcare-associated bacteremia.

Native valve endocarditis is usually caused by viridans streptococci, group D streptococci, *S aureus*, enterococci, or HACEK organisms (an acronym for *Haemophilus aphrophilus, Haemophilus parainfluenzae, Actinobacillus actinomycetemcomitans, Cardiobacterium hominis, Eikenella corrodens,* and *Kingella kingae*). Streptococcal species formerly accounted for the majority of native valve endocarditis cases, but the proportion of cases caused by *S aureus* has been increasing, and this organism is now the leading cause. Gram-negative organisms and fungi account for a small percentage.

In injection drug users, *S aureus* accounts for over 60% of all endocarditis cases and for 80–90% of cases in which the tricuspid valve is infected. Enterococci and streptococci comprise the balance in about equal proportions. Gram-negative aerobic bacilli, fungi, and unusual organisms may cause endocarditis in injection drug users.

The microbiology of prosthetic valve endocarditis also is distinctive. Early infections (ie, those occurring within 2 months after valve implantation) are commonly caused by staphylococci—both coagulase-positive and coagulase-negative—gram-negative organisms, and fungi. In late prosthetic valve endocarditis, streptococci are commonly identified, although coagulase-negative and coagulase-positive staphylococci still cause many cases.

Clinical Findings

Symptoms and Signs

Virtually all patients have fever at some point in the illness, although it may be very low grade (less than 38 °C) in elderly individuals and in patients with heart failure or kidney failure. Rarely, there may be no fever at all.

The duration of illness typically is a few days to a few weeks. Nonspecific symptoms are common. The initial symptoms and signs of endocarditis may be caused by direct arterial, valvular, or cardiac damage. Although a changing regurgitant murmur is significant diagnostically, it is the exception rather than the rule. Symptoms also may occur as a result of embolization, metastatic infection or immunologically mediated phenomena. These include cough; dyspnea; arthralgias or arthritis; diarrhea; and abdominal, back, or flank pain.

The characteristic peripheral lesions—petechiae (on the palate or conjunctiva or beneath the fingernails), subungual ("splinter") hemorrhages, Osler nodes (painful, violaceous raised lesions of the fingers, toes, or feet), Janeway lesions (painless erythematous lesions of the palms or soles), and Roth spots (exudative lesions in the retina)—occur in about 25% of patients (Plates 102 and 103); (see funduscopy). Strokes and major systemic embolic events are present in about 25% of patients, and tend to occur before or within the first week of antimicrobial therapy. Hematuria and proteinuria may result from emboli or immunologically mediated glomerulonephritis, which can cause kidney dysfunction.

Diagnostic Studies

Blood cultures establish the diagnosis. Three sets of blood cultures at least 1 hour apart before starting antibiotics are recommended to maximize the opportunity for a microbiologic diagnosis. Approximately 5% of cases will be culture-negative, usually attributable to administration of antimicrobials prior to obtaining cultures. If antimicrobial therapy has been administered prior to obtaining cultures and the patient is clinically stable, it is reasonable to withhold further antimicrobial therapy for 2–3 days so that appropriate cultures can be obtained. Culture-negative endocarditis may also be due to a fungus, organisms that require special media for growth (eg, *Legionella*, *Bartonella*, *Abiotrophia* species, formerly referred to as nutritionally deficient streptococci), organisms that do not grow on artificial media (*Tropheryma whippelii*, or pathogens of Q fever or psittacosis), or those that are slow-growing and may require prolonged incubation (eg, *Brucella*, anaerobes, HACEK organisms). *Bartonella quintana* has emerged as an important cause of culture-negative endocarditis.

Chest radiograph may show evidence for the underlying cardiac abnormality and, in right-sided endocarditis, pulmonary infiltrates. The electrocardiogram is nondiagnostic, but new conduction abnormalities suggest myocardial abscess formation. Echocardiography is useful in identifying vegetations and other characteristic features suspicious for endocarditis and may provide adjunctive information about the specific valve or valves that are infected. The sensitivity of transthoracic echocardiography is between 55% and 65%; it cannot reliably rule out endocarditis but may confirm a clinical suspicion. TEE is 90% sensitive in detecting vegetations and is particularly useful for identifying valve ring abscesses as well as prosthetic valve endocarditis.

Echocardiography is useful in diagnosis and may provide adjunctive information about the specific valve or valves that are infected. The reported sensitivity of transthoracic echocardiography is between 55% and 65%; it cannot reliably rule out endocarditis but may confirm a clinical suspicion. TEE is 90% sensitive in detecting vegetations and is particularly useful for identifying valve ring abscesses as well as pulmonary and prosthetic valve endocarditis.

Clinical criteria, referred to as the **Modified Duke criteria,** for the diagnosis of endocarditis have been proposed. Major criteria include: (1) two positive blood cultures for a microorganism that typically causes infective endocarditis or persistent bacteremia; (2) evidence of endocardial involvement documented by echocardiography (eg, definite vegetation, myocardial abscess, or new partial dehiscence of a prosthetic valve); or (3) development of a new regurgitant murmur. Minor criteria include the presence of a predisposing condition; fever 38 °C; vascular phenomena, such as cutaneous hemorrhages, aneurysm, systemic emboli, pulmonary infarction; immunologic phenomena, such as glomerulonephritis, Osler nodes, Roth spots, rheumatoid factor; and positive blood cultures not meeting the major criteria or serologic evidence of an active infection. A definite diagnosis can be made with 80% accuracy if two major criteria, one major criterion and three minor criteria, or five minor criteria are fulfilled. A possible diagnosis of endocarditis is made if one major and one minor criterion or three minor criteria are met. If fewer criteria are found, or a sound alternative explanation for illness is identified, or the endocarditis syndrome has resolved and the patient has defervesced within 4 days, endocarditis is unlikely.

Complications

The course of infective endocarditis is determined by the degree of damage to the heart, by the site of infection (right- versus left-sided, aortic versus mitral valve), by the presence of metastatic foci of infection, by the occurrence of embolization, and by immunologically mediated processes. Destruction of infected heart valves is especially common and precipitous with *S aureus* but can occur with any organism and can progress even after bacteriologic cure. The infection can also extend into the myocardium, resulting in abscesses leading to conduction disturbances, and involving the wall of the aorta, creating sinus of Valsalva aneurysms.

Peripheral embolization to the brain and myocardium may result in infarctions. Embolization to the spleen and kidneys is also common. Peripheral emboli may initiate metastatic infections or may become established in vessel walls, leading to mycotic aneurysms. Right-sided endocarditis, which usually involves the tricuspid valve, causes septic pulmonary emboli, occasionally with infarction and lung abscesses.

Prevention

In 2007, the American Heart Association made major revisions to their recommendation on antibiotic prophylaxis for infective endocarditis. The committee determined that only a few cases of infective endocarditis would be prevented by antibiotic prophylaxis for dental procedures even if the prophylactic therapy were 100% effective. Therefore, they limited their recommendations for prophylaxis to a small group of patients with predisposing congenital or valvular anomalies (Table 33–3) undergoing select dental procedures, operations involving the respiratory tract, or operations of infected skin, skin structure, or musculoskeletal tissue (Table 33–4). Current antimicrobial recommendations are given in Table 33–5.

See Related Guideline from *CURRENT Practice Guidelines in Primary Care 2009*

Table 33–3. Cardiac conditions with high risk of adverse outcomes from endocarditis for which prophylaxis with

dental procedures is recommended.[1,2]
Prosthetic cardiac valve
Previous infective endocarditis
Congenital heart disease (CHD)[3] Unrepaired cyanotic CHD, including palliative shunts and conduits Completely repaired congenital heart defect with prosthetic material or device, whether placed by surgery or by catheter intervention, during the first 6 months after the procedure[4] Repaired CHD with residual defects at the site or adjacent to the site of a prosthetic patch or prosthetic device Cardiac transplantation recipients in whom cardiac valvulopathy develops

Oral	Amoxicillin	2 g 1 hour before procedure
Penicillin allergy	Clindamycin	600 mg 1 hour before procedure
	or	
	Cephalexin	2 g 1 hour before procedure (contraindicated if there is history of a -lactam immediate hypersensitivity reaction)
	or	
	Azithromycin or clarithromycin	500 mg 1 hour before procedure

Parenteral	Ampicillin	2 g IM or IV 30 minutes before procedure
Penicillin allergy	Clindamycin	600 mg IV 1 hour before procedure
	or	
	Cefazolin[2]	1 g IM or IV 30 minutes before procedure (contraindicated if there is history of a -lactam immediate hypersensitivity reaction)

[1] Based on recommendations by the American Heart Association. Circulation. 2007 Oct 9;116(15):1736-54.

[2] For patients undergoing respiratory tract procedures involving incision of respiratory tract mucosa to treat an established infection or a procedure on infected skin, skin structure, or musculoskeletal tissue known or suspected to be caused by *S aureus*, the regimen should contain an anti-staphylococcal penicillin or cephalosporin. Vancomycin can be used to treat patients unable to tolerate a -lactam or if the infection is known or suspected to be caused by a methicillin-resistant strain of *S aureus*.

[3] See Table 33–3 for list of cardiac conditions.

Treatment

Empiric regimens for endocarditis while culture results are pending should include agents active against staphylococci, streptococci, and enterococci. Vancomycin, 1 g every 12 hours intravenously plus ceftriaxone 2 g every 24 hours provides appropriate coverage pending definitive diagnosis.

Viridans Streptococci

For penicillin-susceptible viridans streptococcal endocarditis (ie, MIC 0.1 mcg/mL), penicillin G, 2–3 million units intravenously every 4 hours for 4 weeks, is recommended. The duration of therapy can be shortened to 2 weeks if gentamicin, 1 mg/kg intravenously every 8 hours, is used with penicillin. Ceftriaxone, 2 g once daily intravenously or intramuscularly for 4 weeks, is also effective therapy for penicillin-susceptible strains and is a convenient regimen for home therapy. For the penicillin-allergic patient, vancomycin, 15 mg/kg intravenously every 12 hours for 4 weeks, is given. The 2-week regimen is not recommended for patients with symptoms of more than 3 months' duration or with complications such as myocardial abscess or extracardiac infection. Prosthetic valve endocarditis is treated with a 6-week course of penicillin with at least 2 weeks of gentamicin.

Viridans streptococci relatively resistant to penicillin (ie, MIC > 0.1 mcg/mL but 0.5 mcg/mL) should be treated for 4 weeks. Penicillin G, 3 million units intravenously every 4 hours, is combined with gentamicin, 1 mg/kg intravenously every 8 hours for the first 2 weeks. In the patient with IgE-mediated allergy to penicillin, vancomycin alone, 15 mg/kg every 12 hours for 4 weeks, should be administered.

Endocarditis caused by viridans streptococci with an MIC > 0.5 mcg/mL or by nutritionally deficient streptococci should be treated the same as enterococcal endocarditis (see below).

Other Streptococci

Endocarditis caused by *S pneumoniae*, *S pyogenes* (group A streptococcus), or groups B, C, and G streptococci is unusual. *S pneumoniae* sensitive to penicillin (MIC < 0.1 mcg/mL) can be treated with penicillin alone, 2–3 million units intravenously every 4 hours for 4–6 weeks. Vancomycin should be effective for endocarditis caused by strains resistant to penicillin. Group A streptococcal infection can be treated with penicillin, ceftriaxone, or vancomycin for 4–6 weeks. Groups B, C, and G streptococci tend to be more resistant to penicillin than group A streptococci, and some experts have recommended adding gentamicin, 1 mg/kg intravenously every 8 hours, to penicillin for the first 2 weeks of a 4- to

6-week course. Endocarditis caused by *S bovis* is associated with liver disease and gastrointestinal abnormalities, especially colon cancer. Colonoscopy should be performed to exclude the latter.

Enterococci

For enterococcal endocarditis, penicillin alone is inadequate; either streptomycin or gentamicin must be included in the regimen. Because aminoglycoside resistance occurs in enterococci, susceptibility should be documented. Gentamicin is the aminoglycoside of choice, because streptomycin resistance is more common and the nephrotoxicity of gentamicin is generally more easily managed than the vestibular toxicity of streptomycin. Ampicillin, 2 g intravenously every 4 hours, or penicillin G, 3–4 million units intravenously every 4 hours (or, in the penicillin-allergic patient, vancomycin, 15 mg/kg intravenously every 12 hours), plus gentamicin, 1 mg/kg intravenously every 8 hours, are recommended. The recommended duration of combination therapy is 4–6 weeks (the longer duration for patients with symptoms for more than 3 months, relapse, or prosthetic valve endocarditis), although a study from Sweden found that discontinuing the aminoglycoside before 4 weeks did not reduce efficacy. Experience is more extensive with penicillin and ampicillin than with vancomycin for treatment of enterococcal endocarditis, and penicillin and ampicillin are superior to vancomycin in vitro. Thus, whenever possible, either ampicillin or penicillin should be used.

Endocarditis caused by strains resistant to penicillin, vancomycin, or aminoglycosides is particularly difficult to treat. Such cases should be treated according to recent American Heart Association guidelines (see reference below) and managed in consultation with an infectious diseases specialist.

Staphylococci

For methicillin-susceptible *S aureus*, nafcillin or oxacillin, 1.5–2 g intravenously every 4 hours for 6 weeks, is the preferred therapy. Uncomplicated tricuspid valve endocarditis probably can be treated for 2 weeks with nafcillin or oxacillin alone. For penicillin-allergic patients, cefazolin, 2 g intravenously every 8 hours, or vancomycin, 30 mg/kg/d intravenously divided in two or three doses, may be used. For methicillin-resistant strains, vancomycin remains the preferred agent. Aminoglycoside combination regimens are probably of no benefit and in general should be avoided. The effect of rifampin with antistaphylococcal drugs is variable, and its routine use is not recommended.

Because coagulase-negative staphylococci—a common cause of prosthetic valve endocarditis—are routinely resistant to methicillin, -lactam antibiotics should not be used for this infection unless the isolate is demonstrated to be susceptible. A combination of vancomycin, 30 mg/kg/d intravenously divided in two or three doses for 6 weeks; rifampin, 300 mg every 8 hours for 6 weeks; and gentamicin, 1 mg/kg intravenously every 8 hours for the first 2 weeks is recommended for prosthetic valve infection. If the organism is sensitive to methicillin, either nafcillin or oxacillin or cefazolin can be used in combination with rifampin and gentamicin. Combination therapy with nafcillin or oxacillin (vancomycin for methicillin-resistant strains or patients allergic to -lactams), rifampin, and gentamicin is also recommended for treatment of *S aureus* prosthetic valve infection.

HACEK Organisms

HACEK organisms are slow-growing, fastidious gram-negative coccobacilli or bacilli that are normal oral flora and cause less than 5% of all cases of endocarditis. They may produce -lactamase, and thus the treatment of choice is ceftriaxone (or some other third-generation cephalosporin), 2 g intravenously once daily for 4 weeks. Prosthetic valve endocarditis should be treated for 6 weeks. In the penicillin-allergic patient, experience is limited, but trimethoprim-sulfamethoxazole, quinolones, and aztreonam have in vitro activity and should be considered; desensitization may be preferable.

Role of Surgery

While many cases can be successfully treated medically, operative management is frequently required. Acute heart failure unresponsive to medical therapy is an indication for valve replacement even if active infection is present, especially for aortic valve infection. Infections unresponsive to appropriate antimicrobial therapy after 7–10 days (ie, persistent fevers, positive blood cultures despite therapy) are more likely to be eradicated if the valve is replaced. Surgery is nearly always required for cure of fungal endocarditis and is more often necessary with gram-negative bacilli. It is also indicated when the infection involves the sinus of Valsalva or produces septal abscesses. Recurrent infection with the same organism prompts an operative approach, especially with infected prosthetic valves. Continuing embolization presents a difficult problem when the infection is otherwise responding; surgery may be the proper approach. Particularly challenging is a large and fragile vegetation demonstrated by echo in the absence of embolization. Most clinicians favor an operative approach, vegetectomy with valve repair if the patient is a good candidate. Embolization after bacteriologic cure does not necessarily imply recurrence of endocarditis.

Role of Anticoagulation

Anticoagulation is contraindicated in native valve endocarditis because of an increased risk of intracerebral hemorrhage. The role of anticoagulant therapy during active prosthetic valve endocarditis is more controversial. Reversal of anticoagulation may result in thrombosis of the mechanical prosthesis, particularly in the mitral position. On the other hand, anticoagulation during active prosthetic valve endocarditis caused by *S aureus* has been associated with fatal intracerebral hemorrhage. One approach is to discontinue anticoagulation during the septic phase of *S aureus* prosthetic valve endocarditis. In patients with *S aureus* prosthetic valve endocarditis complicated by a central nervous system embolic event, anticoagulation should be discontinued for the first 2 weeks of therapy. Indications for anticoagulation following prosthetic valve implantation for endocarditis are the same as for patients with prosthetic valves without endocarditis (eg, nonporcine mechanical valves and valves in the mitral position).

Response to Therapy

If infection is caused by viridans streptococci, enterococci, or coagulase-negative staphylococci, defervescence occurs in 3–4 days on average; with *S aureus* or *Pseudomonas aeruginosa*, fever commonly persists for 9–12 days. Blood cultures should be obtained to document sterilization of the blood. Other causes of persistent fever are myocardial or metastatic abscess, sterile embolization, superimposed hospital-acquired infection, and drug reaction. Most relapses occur within 1–2 months after completion of therapy. Obtaining one or two blood cultures during this period is prudent.

Bordetella Pertussis Infection (Whooping Cough)

Essentials of Diagnosis

- Predominantly in infants under age 2 years. Adolescents and adults are an important reservoir of infection.
- Two-week prodromal catarrhal stage of malaise, cough, coryza, and anorexia.
- Paroxysmal cough ending in a high-pitched inspiratory "whoop."
- Absolute lymphocytosis, often striking; culture confirms diagnosis.

General Considerations

Pertussis is an acute infection of the respiratory tract caused by *B pertussis* that is transmitted by respiratory droplets. The incubation period is 7–17 days. Half of all cases occur before age 2 years. Neither immunization nor disease confers lasting immunity to pertussis. Consequently, adults are an important reservoir of the disease.

Clinical Findings

The symptoms of classic pertussis last about 6 weeks and are divided into three consecutive stages. The catarrhal stage is characterized by its insidious onset, with lacrimation, sneezing, and coryza, anorexia and malaise, and a hacking night cough that becomes diurnal. The paroxysmal stage is characterized by bursts of rapid, consecutive coughs followed by a deep, high-pitched inspiration (whoop). The convalescent stage begins 4 weeks after onset of the illness with a decrease in the frequency and severity of paroxysms of cough. The diagnosis often is not considered in adults, who may not have a typical presentation. Cough persisting more than 2 weeks is suggestive. Infection may also be asymptomatic.

The white blood cell count is usually 15,000–20,000/mcL (rarely, as high as 50,000/mcL or more), 60–80% of which are lymphocytes. The diagnosis is established by isolating the organism from nasopharyngeal culture. A special medium (eg, Bordet-Gengou agar) must be requested. Polymerase chain reaction assays for diagnosis of pertussis may be available in some clinical or health department laboratories.

Prevention

Acellular pertussis vaccine is recommended for all infants, combined with diphtheria and tetanus toxoids (DTaP). Infants and susceptible adults with significant exposure should receive prophylaxis with an oral macrolide (see below). In recognition of their importance as a reservoir of disease, vaccination of adolescents and adults against pertussis is now recommended. The FDA licensed two tetanus toxoid, reduced diphtheria toxoid and acellular pertussis vaccine (Tdap) products (BOOSTRIX, GlaxoSmithKline and ADACEL, Sanofi Pasteur) in 2005. Adolescents aged 11–18 years who have completed the DTP or DTaP vaccination series should receive a single dose of either Tdap product instead of Td (tetanus and diphtheria toxoids vaccine) for booster immunization against tetanus, diphtheria, and pertussis. Either vaccine may be used in place of Td for prophylaxis of tetanus in wound management. The ADACEL vaccine is indicated as a one-time dose for booster immunization for pertussis in children and adults (ages 11 through 64 years). It may be used as a replacement dose for one of the Td doses when completing a primary immunization series or in place of Td for tetanus wound prophylaxis. Postpartum women and adults who have not been previously vaccinated with Tdap and who have close contact to an infant younger than 12 months should receive a single dose of Tdap. Women of childbearing age are also candidates for one dose of Tdap.

Treatment

Erythromycin, 500 mg four times a day orally for 7 days, shortens the duration of carriage. It also may diminish the severity of coughing paroxysms. Azithromycin, 500 mg orally on day 1 and 250 mg for 4 more days; or clarithromycin, 500 mg orally twice daily for 7 days, is probably as effective as erythromycin and likely to be better tolerated. Trimethoprim-sulfamethoxazole 160 mg-800 mg orally twice a day for 7 days also is effective. These same regimens are indicated for prophylaxis of contacts to an active case of pertussis who are exposed within 3 weeks of the onset of cough in the index case.

Other *Bordetella* Infections

Bordetella bronchiseptica is a pleomorphic gram-negative coccobacillus causing kennel cough in dogs. On occasion it causes upper and lower respiratory infection in humans, principally HIV-infected patients. Infection has been associated with contact with dogs and cats, suggesting animal-to-human transmission. Treatment of *B bronchiseptica* infection is guided by results of in vitro susceptibility tests.

Meningococcal Meningitis

Essentials of Diagnosis

- Fever, headache, vomiting, confusion, delirium, convulsions.
- Petechial rash of skin and mucous membranes in many.
- Neck and back stiffness with positive Kernig and Brudzinski signs is characteristic.
- Purulent spinal fluid with gram-negative intracellular and extracellular diplococci.
- Culture of cerebrospinal fluid, blood, or petechial aspiration confirms the diagnosis.

General Considerations

Meningococcal meningitis is caused by *Neisseria meningitidis* of groups A, B, C, Y, and W-135, among others. Meningitis due to serogroup A is uncommon in the United States. Serogroup B generally causes sporadic cases. The frequency of outbreaks of meningitis caused by group C meningococcus has increased, and this serotype is the most common cause of epidemic disease in the United States. Up to 40% of persons are nasopharyngeal carriers of meningococci, but disease develops in relatively few of these persons. Infection is transmitted by droplets. The clinical illness may take the form of meningococcemia (a fulminant form of septicemia without meningitis), meningococcemia with meningitis, or meningitis. Recurrent meningococcemia with fever, rash, and arthritis is seen rarely in patients with certain terminal complement deficiencies.

Clinical Findings

Symptoms and Signs

High fever, chills, and headache; back, abdominal, and extremity pains; and nausea and vomiting are typical. Rapidly developing confusion, delirium, seizures, and coma occur in some.

On examination, nuchal and back rigidity are typical, with positive Kernig and Brudzinski signs. (Kernig sign is pain in the hamstrings upon extension of the knee with the hip at 90-degree flexion; Brudzinski sign is flexion of the knee in response to flexion of the neck.) A petechial rash appearing in the lower extremities and at pressure points is found in most cases. Petechiae may vary in size from pinpoint lesions to large ecchymoses or even skin gangrene that may later slough if the patient survives.

Laboratory Findings

Lumbar puncture typically reveals a cloudy or purulent cerebrospinal fluid, with elevated pressure, increased protein, and decreased glucose content. The fluid usually contains more than 1000 cells/mcL, with polymorphonuclear cells predominating and containing gram-negative intracellular diplococci. The absence of organisms in a Gram-stained smear of the cerebrospinal fluid sediment does not rule out the diagnosis. The capsular polysaccharide can be demonstrated in cerebrospinal fluid or urine by latex agglutination; this is useful in partially treated patients, though sensitivity is 60–80%. The organism is usually demonstrated by smear and culture of the cerebrospinal fluid, oropharynx, blood, or aspirated petechiae.

Disseminated intravascular coagulation is an important complication of meningococcal infection and is typically present in toxic patients with ecchymotic skin lesions.

Differential Diagnosis

Meningococcal meningitis must be differentiated from other meningitides. In small infants and in the elderly, fever or stiff neck is often missing, and altered mental status may dominate the picture.

Rickettsial, echovirus and, rarely, other bacterial infections (eg, staphylococcal infections, scarlet fever) also cause petechial rash.

Prevention

Two vaccines, meningococcal polysaccharide vaccine (MPSV4, indicated for vaccination of persons over age 55) and a conjugate vaccine (MCV4, indicated for persons aged 2–55 years) are effective for meningococcal groups A, C, Y, and W-135. The Advisory Committee on Immunization Practices recommends immunization with a single dose of MCV4 for preadolescents ages 11–12, and for those not previously vaccinated, upon entry into high school. MCV4 is also recommended for college freshmen—particularly those living in dormitories (see Tables 30–12 and 30–13). Vaccine is also recommended for military recruits, asplenic individuals, those with deficiencies in terminal component of complement, and exposed persons during outbreaks.

Eliminating nasopharyngeal carriage of meningococci is an effective prevention strategy in closed populations and to prevent secondary cases in household or otherwise close contacts. Rifampin, 600 mg orally twice a day for 2 days, ciprofloxacin, 500 mg orally once, or one intramuscular 250-mg dose of ceftriaxone is effective. A cluster of cases of fluoroquinolone-resistant meningococcal infections was recently identified in the United States. However, ciprofloxacin remains a recommended empiric agent for eradication of nasopharyngeal carriage. School and work contacts ordinarily need not be treated. Hospital contacts receive therapy only if intense exposure has occurred (eg, mouth-to-mouth resuscitation). Accidentally discovered carriers without known close contact with meningococcal disease do not require prophylactic antimicrobials.

Treatment

Blood cultures must be obtained and intravenous antimicrobial therapy started immediately. This may be done prior to lumbar puncture in patients in whom the diagnosis is not straightforward and for those in whom MR or CT imaging is indicated to exclude mass lesions. Aqueous penicillin G is the antibiotic of choice (24 million units/24 h intravenously in divided doses every 4 hours). The prevalence of strains of *N meningitidis* with intermediate resistance to penicillin in vitro (MICs 0.1 to 1 mcg/mL) is increasing, particularly in Europe. At what level of resistance penicillin treatment failure can occur is not known. Penicillin-intermediate strains thus far remain fully susceptible to ceftriaxone and other third-generation cephalosporins used to treat meningitis, and these should be effective alternatives to penicillin. In penicillin-allergic patients or those in whom *Haemophilus influenzae* or gram-negative meningitis is a consideration, ceftriaxone, 2 g intravenously every 12 hours, should be used. Treatment should be continued in full doses by the intravenous route until the patient is afebrile for 5 days. Shorter courses—as few as 4 days if ceftriaxone is used—are also effective.

Stephens DS et al. Epidemic meningitis, meningococcaemia, and *Neisseria meningitidis*. Lancet. 2007 Jun 30;369(9580):2196–210. [PMID: 17604802]

Infections Caused by *Haemophilus* Species

H influenzae and other *Haemophilus* species may cause sinusitis, otitis, bronchitis, epiglottitis, pneumonia, cellulitis, arthritis, meningitis, and endocarditis. Nontypeable strains are responsible for most disease in adults. Alcoholism, smoking, chronic lung disease, advanced age, and HIV infection are risk factors.

Haemophilus species colonize the upper respiratory tract in patients with chronic obstructive pulmonary disease and frequently cause purulent bronchitis.

-Lactamase-producing strains are less common in adults than in children. For adults with sinusitis, otitis, or respiratory tract infection, oral amoxicillin, 750 mg twice daily for 10–14 days, is adequate. For -lactamase-producing strains, use of the oral fixed drug combination of amoxicillin, 875 mg, with clavulanate, 125 mg, is indicated. For the penicillin-allergic patient, oral cefuroxime axetil, 250 mg twice daily; trimethoprim-sulfamethoxazole, 800/160 mg orally twice daily; or a fluoroquinolone (ciprofloxacin, 500 mg orally twice daily; levofloxacin, 500 mg orally once daily; or moxifloxacin, 400 mg orally once daily) for 10 days is effective. Azithromycin and clarithromycin are less effective.

In the more seriously ill patient (eg, the toxic patient with multilobar pneumonia) ceftriaxone, 1 g/d intravenously is recommended pending determination of whether the infecting strain is a -lactamase producer. Trimethoprim-sulfamethoxazole administered intravenously based on a dose of 10 mg/kg/d of trimethoprim or a fluoroquinolone (see above for dosage) can be used for the penicillin-allergic patient. A 10- to 14-

day course of therapy is adequate for most cases.

Epiglottitis is characterized by an abrupt onset of high fever, drooling, and inability to handle secretions. An important clue to the diagnosis is complaint of a severe sore throat despite an unimpressive examination of the pharynx. Stridor and respiratory distress result from laryngeal obstruction. The diagnosis is best made by direct visualization of the cherry-red, swollen epiglottis at laryngoscopy. Because laryngoscopy may provoke laryngospasm and obstruction, especially in children, it should be performed in an intensive care unit or similar setting, and only at a time when intubation can be performed promptly. Ceftriaxone, 1 g intravenously every 24 hours for 7–10 days, is the drug of choice. Trimethoprim-sulfamethoxazole or a fluoroquinolone (see above for dosage) may be used in the patient with serious penicillin allergy.

Meningitis , rare in adults, is a consideration in the patient who has meningitis associated with sinusitis or otitis. Initial therapy for suspected *H influenzae* meningitis should be with ceftriaxone, 4 g/d in two divided doses, until the strain is proved not to produce -lactamase. Meningitis is treated for 10–14 days. Dexamethasone, 0.15 mg/kg intravenously every 6 hours may reduce the incidence of long-term sequelae, principally hearing loss.

Tristam S et al. Antimicrobial resistance in *Haemophilus influenzae*. Clin Microbiol Rev. 2007 Apr;20(2):368-89. [PMID: 17428889]

Infections Caused by *Moraxella Catarrhalis*

M catarrhalis is a gram-negative aerobic coccus morphologically and biochemically similar to *Neisseria*. It causes sinusitis, bronchitis, and pneumonia. Bacteremia and meningitis have also been reported in immunocompromised patients. The organism frequently colonizes the respiratory tract, making differentiation of colonization from infection difficult. If *M catarrhalis* is the predominant isolate, therapy is directed against it. *M catarrhalis* typically produces -lactamase and therefore is usually resistant to ampicillin and amoxicillin. It is susceptible to amoxicillin-clavulanate, ampicillin-sulbactam, trimethoprim-sulfamethoxazole, ciprofloxacin, and second- and third-generation cephalosporins.

Heininger N et al. A reservoir of *Moraxella catarrhalis* in human pharyngeal lymphoid tissue. J Infect Dis. 2007 Oct 1;196(7):1080–7. [PMID: 17763332]

Legionnaires Disease

Essentials of Diagnosis

- Patients are often immunocompromised, smokers, or have chronic lung disease.

- Scant sputum production, pleuritic chest pain, toxic appearance.
- Chest radiograph shows focal patchy infiltrates or consolidation.
- Gram stain of sputum shows polymorphonuclear leukocytes and no organisms.

General Considerations

Legionella infection ranks among the three or four most common causes of community-acquired pneumonia and is considered whenever the etiology of a pneumonia is in question. Legionnaires disease is more common in immunocompromised persons, in smokers, and in those with chronic lung disease. Outbreaks have been associated with contaminated water sources, such as showerheads and faucets in patient rooms and air conditioning cooling towers.

Clinical Findings

Symptoms and Signs

Legionnaires disease is one of the atypical pneumonias, so called because a Gram-stained smear of sputum does not show organisms. However, many features of Legionnaires disease are more like typical pneumonia, with high fevers, a toxic patient, pleurisy, and grossly purulent sputum. Classically, this pneumonia is caused by *Legionella pneumophila*, though other species can cause identical disease.

Laboratory Findings

Several laboratory abnormalities can be associated with Legionnaires disease, which include hyponatremia, elevated liver enzymes, and elevated creatine kinase. Culture of *Legionella* species onto charcoal-yeast extract agar or similar enriched medium is the most sensitive method (80–90% sensitivity) for diagnosis and permits identification of infections caused by species and serotypes other than *L pneumophila* serotype 1. Dieterle silver staining of tissue, pleural fluid, or other infected material is also a reliable method for detecting *Legionella* species. Direct fluorescent antibody stains and serologic testing are less sensitive because these will detect only *L pneumophila* serotype 1. In addition, making a serologic diagnosis requires that the host respond with sufficient specific antibody production. Urinary antigen tests, which are targeted for detection of *L pneumophila* serotype 1, are also less sensitive than culture.

Treatment

Azithromycin (500 mg orally once daily), clarithromycin (500 mg orally twice daily), or a fluoroquinolone (eg, levofloxacin 500 mg orally once daily), and not erythromycin, are the drugs of choice for treatment of legionellosis because of their excellent intracellular penetration and in vitro activity, as well as desirable pharmacokinetic properties that permit oral administration and once or twice daily dosing. Duration of therapy is 10–14 days, although a 21-day course of therapy is recommended for immunocompromised patients.

Gram-Negative Bacteremia & Sepsis

Gram-negative bacteremia can originate in a number of sites, the most common being the genitourinary system, hepatobiliary tract, gastrointestinal tract, and lungs. Less common sources include intravenous lines, infusion fluids, surgical wounds, drains, and decubitus ulcers.

Patients with potentially fatal underlying conditions in the short term such as neutropenia or immunoparesis have a mortality rate of 40–60%; those with serious underlying diseases likely to be fatal in 5 years, such as solid tumors, cirrhosis, and aplastic anemia, die in 15–20% of cases; and individuals with no underlying diseases have a mortality rate of 5% or less.

Clinical Findings

Symptoms and Signs

Most patients have fevers and chills, often with abrupt onset. However, 15% of patients are hypothermic (temperature 36.4 °C) at presentation, and 5% never develop a temperature above 37.5 °C. Hyperventilation with respiratory alkalosis and changes in mental status are important early manifestations. Hypotension and shock, which occur in 20–50% of patients, are unfavorable prognostic signs.

Laboratory Findings

Neutropenia or neutrophilia, often with increased numbers of immature forms of polymorphonuclear leukocytes, is the most common laboratory abnormality in septic patients. Thrombocytopenia occurs in 50% of patients, laboratory evidence of coagulation abnormalities in 10%, and overt disseminated intravascular coagulation in 2–3%. Both clinical manifestations and the laboratory abnormalities are nonspecific and insensitive, which accounts for the relatively low rate of blood culture positivity (approximately 20–40%). If possible, three blood cultures from separate sites should be obtained in rapid succession before starting antimicrobial therapy.

The chance of recovering the organism in at least one of the three blood cultures is greater than 95%. The false-negative rate for a single culture of 5–10 mL of blood is 30%. This may be reduced to 5–10% (albeit with a slight false-positive rate due to isolation of contaminants) if a single volume of 30 mL is inoculated into several blood culture bottles. Because blood cultures may be falsely negative, when a patient with presumed septic shock, negative blood cultures, and inadequate explanation for the clinical course responds to antimicrobials, therapy should be continued for 10–14 days.

Treatment

Several factors are important in the management of patients with sepsis.

Removal of Predisposing Factors

This usually means decreasing or stopping immunosuppressive medications and in certain circumstances (eg, positive blood cultures) giving granulocyte colony-stimulating factor (filgrastim; G-CSF) to the neutropenic patient.

Identifying the Source of Bacteremia

By simply finding the source of bacteremia and removing it (intravenous line) or draining it (abscess), a fatal disease becomes easily treatable.

Supportive Measures

The use of fluids and pressors for maintaining blood pressure is discussed in Chapter 12: Blood Vessel & Lymphatic Disorders; management of disseminated intravascular coagulation is discussed in Chapter 13: Blood Disorders.

Antibiotics

Antibiotics should be given as soon as the diagnosis is suspected, since delays in therapy have been associated with increased mortality rates, particularly once hypotension develops. In general, bactericidal antibiotics should be used and given intravenously to ensure therapeutic serum levels. Penetration of antibiotics into the site of primary infection is critical for successful therapy—ie, if the infection originates in the central nervous system, antibiotics that penetrate the blood-brain barrier should be used—eg, penicillin, ampicillin, chloramphenicol, and third-generation cephalosporins—but not first-generation cephalosporins or aminoglycosides, which penetrate poorly. Sepsis caused by gram-positive organisms cannot be differentiated on clinical grounds from that due to gram-negative bacteria. Therefore, initial therapy should include antibiotics active against both types of organisms.

The number of antibiotics necessary remains controversial and depends on the cause. Table 30–9 provides a guide for empiric therapy. Although a combination of antibiotics is often recommended for "synergism," combination therapy has not been shown to be superior to a single-drug regimen with any of several broad-spectrum antibiotics (eg, a third-generation cephalosporin, piperacillin-tazobactam, carbapenem). If multiple drugs are used initially, the regimen should be modified and coverage narrowed based on the results of culture and sensitivity testing.

Corticosteroids

The role of corticosteroids in treatment of septic shock is still quite controversial. Clinical data have suggested an association between mortality in patients with septic shock and poor adrenal reserve to cosyntropin (Cortrosyn) stimulation testing. Administration of "stress doses" of hydrocortisone to patients with relative adrenal insufficiency and pressor-dependent septic shock was shown to reduce mortality in earlier studies. However, the CORTICUS trial, the largest randomized control trial to evaluate the effect of stress-dose hydrocortisone on mortality in septic shock, refuted these earlier findings. This study failed to demonstrate a survival benefit from the addition of stress-dose hydrocortisone, 50 mg intravenously four times a day for 5 days followed by a 6-day tapering dose regimen, in subjects with or without a normal cosyntropin stimulation test. The usefulness of cosyntropin stimulation testing and use of stress-dose hydrocortisone in patients with septic shock are therefore not considered to be standard care.

Adjunctive Therapy

Expanded knowledge of the pathophysiology of sepsis and septic shock and recognition that cytokines play a critical role suggest novel approaches to therapy. Strategies include blocking the effects of endotoxin with anti-endotoxin monoclonal antibodies; blockade of TNF- , a potent cytokine mediator of septic shock, with anti-TNF monoclonal antibody or soluble TNF receptor; use of IL-1 receptor antagonists to inhibit the proinflammatory effects of IL-1 binding to its receptor; use of corticosteroids; and blocking platelet or thrombin activation. None of these strategies have been met with improved survival. However, a single randomized placebo-controlled trial showed that recombinant human activated protein C (drotrecogin alfa) reduced mortality of septic patients with APACHE II scores 25, but the benefits of this agent remain controversial. This drug should be used cautiously because of the risk of bleeding. Drotrecogin alfa is not beneficial for patients with severe sepsis and low risk of death (eg, APACHE II score < 25 or single organ failure), and since it is associated with serious bleeding complications, it should not be used in these patients. Patients considered to have an infectious cause of severe sepsis (defined as three or more signs of systemic inflammation—eg, fever or hypothermia, tachycardia, tachypnea—plus sepsis-induced dysfunction of at least one organ system) of less than 24 hours' duration are the best candidates. Platelet counts less than 30,000/mcL, conditions associated with an increased risk of bleeding (eg, recent trauma, surgery, or bleeding episode; anticoagulation), or hypercoagulable states have not been investigated. These criteria should be followed when selecting candidates for treatment with drotrecogin alfa (activated). The agent is administered intravenously by constant infusion at a dosage of 24 mcg/kg/h for 96 hours.

Salmonellosis: Introduction

Salmonellosis includes infection by any of approximately 2000 serotypes of salmonellae. The taxonomy of *Salmonella* species has been confusing. All *Salmonella* serotypes are members of a single species, *Salmonella enterica*. Human infections are caused almost exclusively by *S enterica* subsp *enterica*, of which three serotypes—typhi, typhimurium, and choleraesuis—are predominantly isolated. Three clinical patterns of infection are recognized: (1) enteric fever, the best example of which is typhoid fever, due to serotype typhi; (2) acute enterocolitis, caused by serotype typhimurium, among others; and (3) the "septicemic" type, characterized by bacteremia and focal lesions, exemplified by infection with serotype choleraesuis. All types are transmitted by ingestion of the organism, usually from contaminated food or drink.

Aligeti VR et al. Primary gluteal abscess due to Salmonella typhimurium: a case report and review of the literature. Am J Med Sci. 2007 Feb;333(2):128–30. [PMID: 17301595]

Enteric Fever (Typhoid Fever)

Essentials of Diagnosis

- Gradual onset of malaise, headache, nausea, vomiting, abdominal pain.
- Rose spots, relative bradycardia, splenomegaly, and abdominal distention and tenderness.
- Slow (stepladder) rise of fever to maximum and then slow return to normal.

- Leukopenia; blood, stool, and urine culture positive for salmonella.

General Considerations

Enteric fever is a clinical syndrome characterized by constitutional and gastrointestinal symptoms and by headache. It can be caused by any *Salmonella* species. The term "typhoid fever" applies when serotype typhi is the cause. Infection is transmitted by consumption of contaminated food or drink. The incubation period is 5–14 days. *Salmonella* is an intracellular pathogen. Infection begins when organisms breach the mucosal epithelium of the intestines by transcytosis, an organism-mediated transport process through the cell via an endocytic vesicle. Having crossed the epithelial barrier, organisms invade and replicate in macrophages in Peyer patches, mesenteric lymph nodes, and the spleen. Serotypes other than typhi usually do not cause invasive disease, presumably because they lack the necessary human-specific virulence factors. Bacteremia occurs, and the infection then localizes principally in the lymphoid tissue of the small intestine (particularly within 60 cm of the ileocecal valve). Peyer patches become inflamed and may ulcerate, with involvement greatest during the third week of disease. The organism may disseminate to the lungs, gallbladder, kidneys, or central nervous system.

Clinical Findings

Symptoms and Signs

During the prodromal stage, there is increasing malaise, headache, cough, and sore throat, often with abdominal pain and constipation, while the fever ascends in a stepwise fashion. After about 7–10 days, it reaches a plateau and the patient is much more ill, appearing exhausted and often prostrated. There may be marked constipation, especially early, or "pea soup" diarrhea; marked abdominal distention occurs as well. If there are no complications, the patient's condition will gradually improve over 7–10 days. However, relapse may occur for up to 2 weeks after defervescence.

During the early prodrome, physical findings are few. Later, splenomegaly, abdominal distention and tenderness, relative bradycardia, and occasionally meningismus appear. The rash (rose spots) commonly appears during the second week of disease. The individual spot, found principally on the trunk, is a pink papule 2–3 mm in diameter that fades on pressure. It disappears in 3–4 days.

Laboratory Findings

Typhoid fever is best diagnosed by blood culture, which is positive in the first week of illness in 80% of patients who have not taken antimicrobials. The rate of positivity declines thereafter, but one-fourth or more of patients still have positive blood cultures in the third week. Cultures of bone marrow occasionally are positive when blood cultures are not. Stool culture is unreliable because it may be positive in gastroenteritis without typhoid fever. Relative bradycardia and leukopenia are typical.

Differential Diagnosis

Enteric fever must be distinguished from other gastrointestinal illnesses and from other infections that have few localizing findings. Examples include tuberculosis, infective endocarditis, brucellosis, lymphoma, and Q fever. Often there is a history of recent travel to endemic areas, and viral hepatitis, malaria, or amebiasis may be in the differential as well.

Complications

Complications occur in about 30% of untreated cases and account for 75% of deaths. Intestinal hemorrhage, manifested by a sudden drop in temperature and signs of shock followed by dark or fresh blood in the stool, or intestinal perforation, accompanied by abdominal pain and tenderness, is most likely to occur during the third week. Appearance of leukocytosis and tachycardia should suggest these complications. Urinary retention, pneumonia, thrombophlebitis, myocarditis, psychosis, cholecystitis, nephritis, osteomyelitis, and meningitis are less often observed.

Prevention

Immunization is not always effective but should be considered for household contacts of a typhoid carrier, for travelers to endemic areas, and during epidemic outbreaks. A multiple-dose oral vaccine and a single-dose parenteral vaccine are available. Their efficacies are similar, but oral vaccine causes fewer side effects. Boosters, when indicated, should be given every 5 years and 2 years for oral and parenteral preparations, respectively.

Adequate waste disposal and protection of food and water supplies from contamination are important public health measures to prevent salmonellosis. Carriers cannot work as food handlers.

Treatment

Specific Measures

Several antibiotics, including ampicillin, azithromycin, chloramphenicol, third-generation cephalosporins, and trimethoprim-sulfamethoxazole all are effective for treatment of enteric fever caused by drug-susceptible strains. These drugs can be given orally or intravenously depending on the patient's condition. Because many salmonella strains are resistant to ampicillin, chloramphenicol, and trimethoprim-sulfamethoxazole, a fluoroquinolone—such as ciprofloxacin 750 mg orally twice daily or levofloxacin 500 mg orally once daily, 5–7 days for uncomplicated enteric fever and 10–14 days for severe infection—is the agent of choice for treatment of salmonella infections. Ceftriaxone, 2 g intravenously for 7 days, is also effective. Although resistance to fluoroquinolones or cephalosporins occurs uncommonly, the prevalence appears to be increasing. When an infection is caused by a multidrug-resistant strain, select an antibiotic to which the isolate is susceptible in vitro. Alternatively, increasing the dose of ceftriaxone to 4 g/d and treating for 10–14 days or using azithromycin 500 mg orally for 7 days in uncomplicated cases may be effective.

Treatment of Carriers

Chemotherapy often is unsuccessful in eradicating the carrier state. While treatment of carriage with ampicillin, trimethoprim-sulfamethoxazole, or chloramphenicol may be successful, ciprofloxacin, 750 mg orally twice a day for 4 weeks, has proved to be highly effective. Cholecystectomy may also achieve this goal.

Prognosis

The mortality rate of typhoid fever is about 2% in treated cases. Elderly or debilitated persons are likely to do poorly. With complications, the prognosis is poor.

Relapses occur in up to 15% of cases. A residual carrier state frequently persists in spite of chemotherapy.

Parry CM et al. A randomised controlled comparison of ofloxacin, azithromycin and an ofloxacin-azithromycin combination for treatment of multidrug-resistant and nalidixic acid resistant typhoid fever. Antimicrob Agents Chemother. 2007 Mar;51(3):819–25. [PMID: 17145784]

Salmonella Gastroenteritis

By far the most common form of salmonellosis is acute enterocolitis caused by numerous *Salmonella* serotypes. The incubation period is 8–48 hours after ingestion of contaminated food or liquid.

Symptoms and signs consist of fever (often with chills), nausea and vomiting, cramping abdominal pain, and diarrhea, which may be grossly bloody, lasting 3–5 days. Differentiation must be made from viral gastroenteritis, food poisoning, shigellosis, amebic dysentery, and acute ulcerative colitis. The diagnosis is made by culturing the organism from the stool.

The disease is usually self-limited, but bacteremia with localization in joints or bones may occur, especially in patients with sickle cell disease.

Treatment of uncomplicated enterocolitis is symptomatic only. Malnourished or severely ill patients, those with sickle cell disease, and HIV-positive patients should be treated for 3–5 days with trimethoprim-sulfamethoxazole (one double-strength tablet twice a day), ampicillin (100 mg/kg intravenously or orally), or ciprofloxacin (750 mg orally twice a day).

Swanson SJ et al. Multidrug-resistant *Salmonella enterica* serotype *Typhimurium* associated with pet rodents. N Engl J Med. 2007 Jan 4;356(1):21–8. [PMID: 17202452]

Salmonella Bacteremia

Salmonella infection may be manifested by prolonged or recurrent fevers accompanied by bacteremia and local infection in bone, joints, pleura, pericardium, lungs, or other sites. Mycotic abdominal aortic aneurysms may also occur. Serotypes other than typhi usually are isolated. This complication tends to occur in immunocompromised persons and is seen in HIV-infected individuals, who typically have bacteremia without an obvious source. Treatment is the same as for typhoid fever, plus drainage of any abscesses. In HIV-infected patients, relapse is common, and lifelong suppressive therapy may be needed. Ciprofloxacin, 750 mg orally twice a day, is effective both for therapy of acute infection and for suppression of recurrence. Incidence of infections caused by drug-resistant strains may be on the rise.

Shigellosis

Essentials of Diagnosis

- Diarrhea, often with blood and mucus.
- Crampy abdominal pain and systemic toxicity.
- White blood cells in stools; organism isolated on stool culture.

General Considerations

Shigella dysentery is a common disease, often self-limited and mild but occasionally serious. *Shigella sonnei* is the leading cause in the United States, followed by *Shigella flexneri*. *Shigella dysenteriae* causes the most serious form of the illness. Shigellae are invasive organisms. The infective dose is 10^2–10^3 organisms. There has been a rise in strains resistant to multiple antibiotics.

Clinical Findings

Symptoms and Signs

The illness usually starts abruptly, with diarrhea, lower abdominal cramps, and tenesmus. The diarrheal stool often is mixed with blood and mucus. Systemic symptoms are fever, chills, anorexia and malaise, and headache. The abdomen is tender. Sigmoidoscopic examination reveals an inflamed, engorged mucosa with punctate and sometimes large areas of ulceration.

Laboratory Findings

The stool shows many leukocytes and red cells. Stool culture is positive for shigellae in most cases, but blood cultures grow the organism in less than 5% of cases.

Differential Diagnosis

Bacillary dysentery must be distinguished from salmonella enterocolitis and from disease due to enterotoxigenic *Escherichia coli, Campylobacter*, and *Yersinia enterocolitica.* Amebic dysentery may be similar clinically and is diagnosed by finding amebas in the fresh stool specimen. Ulcerative colitis is also an important cause of bloody diarrhea.

Complications

Temporary disaccharidase deficiency may follow the diarrhea. Reactive arthritis is an uncommon complication, usually occurring in HLA-B27 individuals infected by *Shigella*. Hemolytic-uremic syndrome occurs rarely.

Treatment

Treatment of dehydration and hypotension is lifesaving in severe cases. The antimicrobial treatments of choice are trimethoprim-sulfamethoxazole, one double-strength tablet twice a day for 7–10 days, or a fluoroquinolone (ciprofloxacin 750 mg orally twice daily for 7–10 days, or levofloxacin, 500 mg orally once daily) for 3 days. Fluoroquinolones are contraindicated in pregnancy. Shigellae resistant to ampicillin are common, but if the isolate is susceptible, a dose of 500 mg orally four times a day is also effective. Amoxicillin, which is less effective, should not be used.

Aragón TJ et al. Case-control study of shigellosis in San Francisco: the role of sexual transmission and HIV infection. Clin Infect Dis. 2007 Feb 1;44(3):327–34. [PMID: 17205436]

Gastroenteritis Caused by *Escherichia Coli*

E coli causes gastroenteritis by a variety of mechanisms. Enterotoxigenic *E coli* (ETEC) elaborates either a heat-stable or heat-labile toxin that mediates the disease. ETEC is an important cause of traveler's diarrhea. Enteroinvasive *E coli* (EIEC) differs from other *E coli* bowel pathogens in that these strains invade cells, causing bloody diarrhea and dysentery similar to infection with *Shigella* species. EIEC is uncommon in the United States. Neither ETEC nor EIEC strains are routinely isolated and identified from stool cultures because there is no selective medium. Antimicrobial therapy directed against *Salmonella* and *Shigella* shortens the clinical course, but the disease is self-limited.

Enterohemorrhagic *E coli* (EHEC) produces two shiga-like toxins that mediate the clinical manifestations, which include an asymptomatic carriage stage, nonbloody diarrhea, hemorrhagic colitis, hemolytic-uremic syndrome, and thrombotic thrombocytopenic purpura. Although there are several serotypes of EHEC, O157:H7 is responsible for most cases in the United States. *E coli* O157:H7 has caused several outbreaks of diarrhea and hemolytic-uremic syndrome related to consumption of undercooked hamburger and unpasteurized apple juice. Older individuals and young children are most affected, with hemolytic-uremic syndrome being more common in the latter group. *E coli* O157:H7 is not identified by routine stool cultures. Isolation requires identification of sorbitol-negative colonies of *E coli* on sorbitol-MacConkey agar followed by serologic testing to confirm the serotype. Antimicrobial therapy does not alter the course of the disease, and may increase the risk of hemolytic-uremic syndrome. Treatment is primarily supportive. Hemolytic-uremic syndrome or thrombotic thrombocytopenic purpura occurring in association with a diarrheal illness suggests the diagnosis and should prompt evaluation for EHEC. Confirmed infections should be reported to public health officials.

combination with antibiotics on treatment outcomes in traveler's diarrhea: a systematic review and meta-analysis. Clin Infect Dis. 2008 Oct 15;47(8):1007–14. [PMID: 18781873]

Serna A 4th et al. Pathogenesis and treatment of Shiga toxin-producing *Escherichia coli* infections. Curr Opin Gastroenterol. 2008 Jan;24(1):38-47. [PMID: 18043231]

Cholera

Essentials of Diagnosis

- History of travel in endemic area or contact with infected person.
- Voluminous diarrhea.
- Stool is liquid, gray, turbid, and without fecal odor, blood, or pus ("rice water stool").
- Rapid development of marked dehydration.
- Positive stool cultures and agglutination of vibrios with specific sera.

General Considerations

Cholera is an acute diarrheal illness caused by certain serotypes of *Vibrio cholerae.* The disease is toxin-mediated, and fever is unusual. The toxin activates adenylyl cyclase in intestinal epithelial cells of the small intestines, producing hypersecretion of water and chloride ion and a massive diarrhea of up to 15 L/d. Death results from profound hypovolemia.

Cholera occurs in epidemics under conditions of crowding, war, and famine (eg, in refugee camps) and where sanitation is inadequate. Infection is acquired by ingestion of contaminated food or water. Cholera was rarely seen in the United States until 1991, when epidemic cholera returned to the Western Hemisphere, originating as an outbreak in coastal cities of Peru. The epidemic spread to involve several countries in South and Central America as well as Mexico, and cases have been imported into the United States. Cholera should be considered in the differential diagnosis of severe watery diarrhea, especially in those who have traveled to affected countries.

Clinical Findings

Cholera is characterized by a sudden onset of severe, frequent watery diarrhea (up to 1 L/h). The liquid stool is gray; turbid; and without fecal odor, blood, or pus ("rice water stool"). Dehydration and hypotension develop rapidly. Stool cultures are positive, and agglutination of vibrios with specific sera can be demonstrated.

Prevention

A vaccine is available that confers short-lived, limited protection and may be required for entry into or reentry after travel to some countries. It is administered in two doses 1–4 weeks apart. A booster dose every 6 months is recommended for persons remaining in areas where cholera is a hazard.

Vaccination programs are expensive and not particularly effective in managing outbreaks of cholera. When outbreaks occur, efforts should be directed toward establishing clean water and food sources and proper waste disposal.

Treatment

Treatment is by replacement of fluids. In mild or moderate illness, oral rehydration usually is adequate. A simple oral replacement fluid can be made from 1 teaspoon of table salt and 4 heaping teaspoons of sugar added to 1 L of water. Intravenous fluids are indicated for persons with signs of severe hypovolemia and those who cannot take adequate fluids orally. Lactated Ringer infusion is satisfactory.

Antimicrobial therapy will shorten the course of illness. Several antimicrobials are active against *V cholerae*, including tetracycline, ampicillin, chloramphenicol, trimethoprim-sulfamethoxazole, fluoroquinolones, and azithromycin. Multiple drug-resistant strains are increasingly encountered, so susceptibility testing, if available, is advisable. A single 1 g oral dose of azithromycin was effective for severe cholera caused by strains with reduced susceptibility to fluoroquinolones, but resistance is emerging to this drug as well.

Tobin-D'Angelo M et al. Severe diarrhea caused by cholera toxin-producing *Vibrio cholerae* serogroup O75 infections acquired in the southeastern United States. Clin Infect Dis. 2008 Oct 15;47(8):1035–40. [PMID: 18781876]

Zuckerman JN et al. The true burden and risk of cholera: implications for prevention and control. Lancet Infect Dis. 2007 Aug;7(8):521–30. [PMID: 17584531]

Infections Caused by Other *Vibrio* Species

Vibrios other than *V cholerae* that cause human disease are *Vibrio parahaemolyticus*, *Vibrio vulnificus*, and *Vibrio alginolyticus*. All are halophilic marine organisms. Infection is acquired by exposure to organisms in contaminated, undercooked, or raw crustaceans or shellfish and warm (>20 °C) ocean waters and estuaries. Infections are more common during the summer months from regions along the Atlantic coast and the Gulf of Mexico in the United States and from tropical waters around the world. Oysters are implicated in up to 90% of food-related cases. *V parahaemolyticus* causes an acute watery diarrhea with crampy abdominal pain and fever, typically occurring within 24 hours after ingestion of contaminated shellfish. The disease is self-limited, and antimicrobial therapy is usually not necessary. *V parahaemolyticus* may also cause cellulitis and sepsis, though these findings are more characteristic of *V vulnificus* infection.

V vulnificus and *V alginolyticus*—neither of which is associated with diarrheal illness—are important causes of cellulitis and primary bacteremia following ingestion of contaminated shellfish or exposure to sea water. Cellulitis with or without sepsis may be accompanied by bulla formation and necrosis with extensive soft tissue destruction, at times requiring debridement and amputation. The infection can be rapidly progressive and is particularly severe in immunocompromised individuals—especially those with cirrhosis—with death rates as high as 50%. Patients with chronic liver disease and those who are immunocompromised should be cautioned to avoid eating raw oysters.

Tetracycline at a dose of 500 mg orally four times a day for 7–10 days is the drug of choice for treatment of suspected or documented primary bacteremia or cellulitis caused by *Vibrio* species. *V vulnificus* is susceptible in vitro to penicillin, ampicillin, cephalosporins, chloramphenicol, aminoglycosides, and fluoroquinolones, and these agents may also be effective. *V parahaemolyticus* and *V alginolyticus* produce -lactamase and therefore are resistant to penicillin and ampicillin, but susceptibilities otherwise are similar to those listed for *V vulnificus*.

Dechet AM. Nonfoodborne *Vibrio* infections: an important cause of morbidity and mortality in the United States, 1997–2006. Clin Infect Dis. 2008 Apr 1;46(7):970–6. [PMID: 18444811]

Infections Caused by *Campylobacter* Species

Campylobacter organisms are microaerophilic, motile, gram-negative rods. Two species infect humans: *Campylobacter jejuni*, an important cause of diarrheal disease, and *Campylobacter fetus* subsp *fetus*, which typically causes systemic infection and not diarrhea. Dairy cattle and poultry are an important reservoir for campylobacters. Outbreaks of enteritis have been associated with consumption of raw milk. Campylobacter gastroenteritis is associated with fever, abdominal pain, and diarrhea characterized by loose, watery, or bloody stools. The differential diagnosis includes shigellosis, *Salmonella* gastroenteritis, and enteritis caused by *Y enterocolitica* or invasive *E coli*. The disease is self-limited, but its duration can be shortened with antimicrobial therapy. Either azithromycin, 1 g orally as a single dose, or ciprofloxacin, 500 mg orally twice daily for 3 days, is effective therapy. However, fluoroquinolone resistance among *C jejuni* isolates has been increasing and susceptibility testing should be routinely performed.

C fetus causes systemic infections that can be fatal, including primary bacteremia, endocarditis, meningitis, and focal abscesses. It infrequently causes gastroenteritis. Patients infected with *C fetus* are often older, debilitated, or immunocompromised. Closely related species, collectively termed "campylobacter-like organisms," cause bacteremia in HIV-infected individuals. Systemic infections respond to therapy with gentamicin, chloramphenicol, ceftriaxone, or ciprofloxacin. Ceftriaxone or chloramphenicol should be used to treat infections of the central nervous system because of their ability to penetrate the blood-brain barrier.

Brucellosis

Essentials of Diagnosis

- History of animal exposure, ingestion of unpasteurized milk or cheese.
- Insidious onset: easy fatigability, headache, arthralgia, anorexia, sweating, irritability.
- Intermittent and persistent fever.
- Cervical and axillary lymphadenopathy; hepatosplenomegaly.
- Lymphocytosis, positive blood culture, positive serologic test.

General Considerations

The infection is transmitted from animals to humans. *Brucella abortus* (cattle), *Brucella suis* (hogs), and *Brucella melitensis* (goats) are the main agents. Transmission to humans occurs by contact with infected meat (slaughterhouse workers), placentae of infected animals (farmers, veterinarians), or ingestion of infected unpasteurized milk or cheese. The incubation period varies from a few days to several weeks. Brucellosis is a systemic infection that may become chronic. In the United States, brucellosis is very rare. Almost all US cases are imported from countries where brucellosis is endemic (eg, Mexico, Mediterranean Europe, Spain, South American countries).

Clinical Findings

Symptoms and Signs

The onset may be acute, with fever, chills, and sweats, but more often is insidious with symptoms of weakness, weight loss, low-grade fevers, sweats, and exhaustion upon minimal activity. Headache, abdominal or back pain with anorexia and constipation, and arthralgias are also common. The chronic form may assume an undulant nature, with periods of normal temperature between acute attacks; symptoms may persist for years, either continuously or intermittently.

Fever, hepatosplenomegaly, and lymphadenopathy are the most common physical findings. Infection may present with or be complicated by specific organ involvement with signs of endocarditis, meningitis, epididymitis, orchitis, arthritis (especially sacroilitis), spondylitis, or osteomyelitis.

Laboratory Findings

The organism can be recovered from cultures of blood, cerebrospinal fluid, urine, bone marrow, or other sites. Modern automated systems have shortened the time to detection of the organism in blood culture. Cultures are more likely to be negative in chronic cases. The diagnosis often is made by serologic testing. Rising serologic titers or an absolute agglutination titer of greater than 1:160 supports the diagnosis.

Differential Diagnosis

Brucellosis must be differentiated from any other acute febrile disease, especially influenza, tularemia, Q fever, mononucleosis, and enteric fever. In its chronic form it resembles Hodgkin disease, tuberculosis, HIV infection, malaria, and disseminated fungal infections such as histoplasmosis and coccidioidomycosis.

Complications

The most frequent complications are bone and joint lesions such as spondylitis and suppurative arthritis (usually of a single joint), endocarditis, and meningoencephalitis. Less common complications are pneumonitis with pleural effusion, hepatitis, and cholecystitis.

Treatment

Single-drug regimens are not recommended because the relapse rate may be as high as 50%. Combination regimens of two or three drugs are most effective. Regimens of doxycycline (200 mg/d orally for 6 weeks) plus rifampin (600 mg/d orally for 6 weeks) or streptomycin (1 g/d intramuscularly for 2 weeks) or gentamicin (240 mg intramuscularly once daily for 7 days) have the lowest recurrence rates. Longer courses of therapy may be required to prevent relapse of meningitis, osteomyelitis, or endocarditis.

Skalsky K et al. Treatment of human brucellosis: systematic review and meta-analysis of randomised controlled trials. BMJ. 2008 Mar 29;336(7646):701–4. [PMID: 18321957]

Tularemia

Essentials of Diagnosis

- History of contact with rabbits, other rodents, and biting arthropods (eg, ticks in summer) in endemic area.
- Fever, headache, nausea, and prostration.
- Papule progressing to ulcer at site of inoculation.
- Enlarged regional lymph nodes.
- Serologic tests or culture of ulcer, lymph node aspirate, or blood confirm the diagnosis.

General Considerations

Tularemia is a zoonotic infection of wild rodents and rabbits caused by *Francisella tularensis.* Humans usually acquire the infection by contact with animal tissues (eg, trapping muskrats, skinning rabbits) or from a tick or insect bite. Hamsters and prairie dogs also may carry the organism. An investigation of an outbreak of pneumonic tularemia on Martha's Vineyard in Massachusetts implicated lawn-mowing and brush-cutting as risk factors for infection, underscoring the potential for probable aerosol transmission of the organism. *F tularensis* has been classified as a high-priority agent for potential bioterrorism use because of its virulence and relative ease of dissemination. Infection in humans often produces a local lesion and widespread organ involvement but may be entirely asymptomatic. The incubation period is 2–10 days.

Clinical Findings

Symptoms and Signs

Fever, headache, and nausea begin suddenly, and a local lesion—a papule at the site of inoculation—develops and soon ulcerates. Regional lymph nodes may become enlarged and tender and may suppurate. The local lesion may be on the skin of an extremity or in the eye. Pneumonia may develop from hematogenous spread of the organism or may be primary after inhalation of infected aerosols, which are responsible for human-to-human transmission. Following ingestion of infected meat or water, an enteric form may be manifested by gastrointestinal symptoms, stupor, and delirium. In any type of involvement, the spleen may be enlarged and tender and there may be nonspecific rashes, myalgias, and prostration.

Laboratory Findings

Culturing the organism from blood or infected tissue requires special media. For this reason and because cultures of *F tularensis* may be hazardous to laboratory personnel, the diagnosis is usually made serologically. A positive agglutination test (> 1:80) develops in the second week after infection and may persist for several years.

Differential Diagnosis

Tularemia must be differentiated from rickettsial and meningococcal infections, cat-scratch disease, infectious mononucleosis, and various bacterial and fungal diseases.

Complications

Hematogenous spread may produce meningitis, perisplenitis, pericarditis, pneumonia, and osteomyelitis.

Treatment

Streptomycin is drug of choice for treatment of tularemia. The recommended dose is 7.5 mg/kg intramuscularly every 12 hours for 7–14 days. Gentamicin, which has good in vitro activity against *F tularensis*, is generally less toxic than streptomycin and probably just as effective. Doxycycline (200 mg/d orally) is also effective but has a higher relapse rate. A variety of other agents (eg, fluoroquinolones) are active in vitro but their clinical effectiveness is less well established.

Nigrovic LE et al. Tularemia. Infect Dis Clin North Am. 2008 Sep;22(3):489–504. [PMID: 18755386]

Plague

Essentials of Diagnosis

- History of exposure to rodents in endemic area.
- Sudden onset of high fever, malaise, muscular pains, and prostration.
- Axillary or inguinal lymphadenitis (bubo).
- Bacteremia, pneumonitis, and meningitis may occur.
- Positive smear and culture from bubo and positive blood culture.

General Considerations

Plague is an infection of wild rodents with *Yersinia pestis*, a small bipolar-staining gram-negative rod. It is endemic in California, Arizona, Nevada, and New Mexico. It is transmitted among rodents and to humans by the bites of fleas or from contact with infected animals. Following a fleabite, the organisms spread through the lymphatics to the lymph nodes, which become greatly enlarged (bubo).

They may then reach the bloodstream to involve all organs. When pneumonia or meningitis develops, the outcome is often fatal. The patient with pneumonia can transmit the infection to other individuals by droplets. The incubation period is 2–10 days. Because of its extreme virulence, its potential for dissemination and person-to-person transmission, and efforts to develop the organism as an agent of biowarfare, plague bacillus is considered a high-priority agent for bioterrorism.

Clinical Findings

Symptoms and Signs

The onset is sudden, with high fever, malaise, tachycardia, intense headache, delirium, and severe myalgias. The patient appears profoundly ill. If pneumonia develops, tachypnea, productive cough, blood-tinged sputum, and cyanosis also occur. There may be signs of meningitis. A pustule or ulcer at the site of inoculation and lymphangitis may be observed. Axillary, inguinal, or cervical lymph nodes become enlarged and tender and may suppurate and drain. With hematogenous spread, the patient may rapidly become toxic and comatose, with purpuric spots (black plague) appearing on the skin.

Primary plague pneumonia is a fulminant pneumonitis with bloody, frothy sputum and sepsis. It is usually fatal unless treatment is started within a few hours after onset.

Laboratory Findings

The plague bacillus may be found in smears from aspirates of buboes examined with Gram stain. Cultures from bubo aspirate or pus and blood are positive but may grow slowly. In convalescing patients, an antibody titer rise may be demonstrated by agglutination tests.

Differential Diagnosis

The lymphadenitis of plague is most commonly mistaken for the lymphadenitis accompanying staphylococcal or streptococcal infections of an extremity, sexually transmitted diseases such as lymphogranuloma venereum or syphilis, and tularemia. The systemic manifestations resemble those of enteric or rickettsial fevers, malaria, or influenza. The pneumonia resembles other bacterial pneumonias, and the meningitis is similar to those caused by other bacteria.

Prevention

Drug prophylaxis may provide temporary protection for persons exposed to the risk of plague infection, particularly by the respiratory route. Tetracycline hydrochloride, 500 mg orally once or twice daily for 5 days, is effective.

Plague vaccines—both live and killed—have been used for many years, but their efficacy is not clearly established.

Treatment

Therapy should be started immediately once plague is suspected. Either streptomycin (the agent with which there is greatest experience), 1 g every 12 hours intravenously, or gentamicin, administered as a 2-mg/kg loading dose, then 1.7 mg/kg every 8 hours intravenously, is effective. Alternatively, doxycycline, 100 mg orally or intravenously, may be used. The duration of therapy is 10 days. Patients with plague pneumonia are placed in strict respiratory isolation, and prophylactic therapy is given to any person who came in contact with the patient.

Gonococcal Infections

Essentials of Diagnosis

- Purulent and profuse urethral discharge, especially in men, with dysuria, yielding positive smear.
- Epididymitis, prostatitis, periurethral inflammation, proctitis in men.

- Cervicitis in women with purulent discharge, or asymptomatic, yielding positive culture; vaginitis, salpingitis, proctitis also occur.
- Fever, rash, tenosynovitis, and arthritis with disseminated disease.
- Gram-negative intracellular diplococci seen in a smear or cultured from any site, particularly the urethra, cervix, pharynx, and rectum.

General Considerations

Gonorrhea is caused by *Neisseria gonorrhoeae*, a gram-negative diplococcus typically found inside polymorphonuclear cells. It is transmitted during sexual activity and has its greatest incidence in the 15- to 29-year-old age group. The incubation period is usually 2–8 days.

Classification

Urethritis and Cervicitis

In men, there is initially burning on urination and a serous or milky discharge. One to 3 days later, the urethral pain is more pronounced and the discharge becomes yellow, creamy, and profuse, sometimes blood-tinged. The disorder may regress and become chronic or progress to involve the prostate, epididymis, and periurethral glands with painful inflammation. Chronic infection leads to prostatitis and urethral strictures. Rectal infection is common in homosexual men. Atypical sites of primary infection (eg, the pharynx) must always be considered. Asymptomatic infection is common and occurs in both sexes.

Gonococcal infection in women often becomes symptomatic during menses. Women may have dysuria, urinary frequency, and urgency, with a purulent urethral discharge. Vaginitis and cervicitis with inflammation of Bartholin glands are common. Infection may be asymptomatic, with only slightly increased vaginal discharge and moderate cervicitis on examination. Infection may remain as a chronic cervicitis—an important reservoir of gonococci. It can progress to involve the uterus and tubes with acute and chronic salpingitis, with scarring of tubes and sterility. In pelvic inflammatory disease, anaerobes and chlamydiae often accompany gonococci. Rectal infection may result from spread of the organism from the genital tract or from anal coitus.

Gram stain of urethral discharge in men, especially during the first week after onset, shows gram-negative diplococci in polymorphonuclear leukocytes. Gram stain is less often positive in women. Culture has been the gold standard for diagnosis, particularly when the Gram stain is negative. Nucleic acid amplification tests for *N gonorrhoeae* in cervical and urethral swab specimens and urine permit rapid diagnosis, have excellent sensitivity and specificity, and have largely replaced culture. Identification of *N gonorrhoeae* from rectal or pharyngeal sites, blood, and in joint fluid still requires culture.

Disseminated Disease

Systemic complications follow the dissemination of gonococci from the primary site via the bloodstream. Gonococcal bacteremia is associated with intermittent fever, arthralgia, and skin lesions ranging from maculopapular to pustular or hemorrhagic, which tend to be few in number and peripherally located. Rarely, gonococcal endocarditis or meningitis develops. Arthritis and tenosynovitis are common complications, particularly involving the knees, ankles, and wrists. One or occasionally a few joints usually are involved. Gonococci are isolated by culture from less than half of patients with gonococcal arthritis.

Conjunctivitis

The most common form of eye involvement is direct inoculation of gonococci into the conjunctival sac. In adults, this occurs by autoinoculation of a person with genital infection. The purulent conjunctivitis may rapidly progress to panophthalmitis and loss of the eye unless treated promptly. A single 1-g dose of ceftriaxone is effective.

Differential Diagnosis

Gonococcal urethritis or cervicitis must be differentiated from nongonococcal urethritis; cervicitis or vaginitis due to *Chlamydia trachomatis*, *Gardnerella vaginalis*, *Trichomonas*, *Candida*, and many other pathogens associated with sexually transmitted diseases; and pelvic inflammatory disease, arthritis, proctitis, and skin lesions. Often, several such pathogens coexist in a patient. Reactive arthritis (urethritis, conjunctivitis, arthritis) may mimic gonorrhea or coexist with it.

Prevention

Prevention is based on education and mechanical or chemical prophylaxis. The condom, if properly used, can reduce the risk of infection. Effective drugs taken in therapeutic doses within 24 hours of exposure can abort an infection. Partner notification and referral of contacts for treatment has been the standard method used to control sexually transmitted diseases. Expedited treatment of sex partners by patient-delivered partner therapy is more effective than partner notification in reducing persistence and recurrence rates of gonorrhea and chlamydia. This strategy is being increasingly adopted as a means of disease control.

Treatment

Therapy typically is administered before antimicrobial susceptibilities are known. The choice of which regimen to use should be based on the national prevalences of antibiotic-resistant organisms. Nationwide, strains of gonococci that are resistant to penicillin, tetracycline, or ciprofloxacin have been increasingly observed. Consequently, these drugs can no longer be considered first-line therapy. All sexual partners should be treated and tested for HIV infection and syphilis, as should the patient.

Uncomplicated Gonorrhea

For uncomplicated gonococcal infections of the cervix, urethra, and rectum, either ceftriaxone (125 mg intramuscularly) or cefixime (400 mg orally as a single dose) is the treatment of choice. Fluoroquinolones are no longer recommended because of high rates of resistance. Spectinomycin, 1 g intramuscularly once, may be used for the penicillin-allergic patient but is not currently available in the United States. Other single-dose cephalosporin therapies that are considered alternative treatment regimens for uncomplicated urogenital and anorectal gonococcal infections include ceftizoxime, 500 mg intramuscularly once; or cefoxitin, 2 g intramuscularly once, administered with probenecid, 1 g orally; or cefotaxime, 500 mg intramuscularly once. Some evidence indicates that single-dose cefpodoxime, 400 mg and cefuroxime axetil, 1 g might be oral alternatives.

Pharyngeal gonorrhea is treated by ceftriaxone, 125 mg intramuscularly. Since coexistent chlamydial infection is common, doxycycline, 100 mg orally twice daily for 7 days, or azithromycin, given as a single 1-g oral dose, concurrently, should be administered unless chlamydial infection has been ruled out with a negative nucleic acid amplification test for *C trachomatis;* women should have a pregnancy test before a tetracycline (such as doxycycline) is prescribed.

Treatment of Other Infections

Disseminated gonococcal infection should be treated with ceftriaxone, 1 g intravenously daily, until 48 hours after improvement begins, at which time therapy may be switched to cefixime, 400 mg orally daily to complete at least 1 week of antimicrobial therapy. An oral fluoroquinolone (ciprofloxacin, 500 mg twice daily, or levofloxacin, 500 mg once daily) for 7 days also is effective, provided the isolate is susceptible. Endocarditis should be treated with ceftriaxone, 2 g every 24 hours intravenously, for at least 3 weeks. Postgonococcal urethritis and cervicitis, which are usually caused by chlamydia, are treated with a regimen of erythromycin, doxycycline, or azithromycin as described above.

Pelvic inflammatory disease requires cefoxitin, 2 g parenterally every 6 hours, or cefotetan, 2 g intravenously every 12 hours. Clindamycin, 900 mg intravenously every

8 hours, plus gentamicin, administered intravenously as a 2-mg/kg loading dose followed by 1.5 mg/kg every 8 hours, is also effective. Cefoxitin, 2 g intramuscularly, plus probenecid, 1 g orally as a single dose, followed by a 14-day oral regimen of doxycycline, 100 mg twice a day, with or without metronidazole, 500 mg twice daily, is an effective outpatient regimen. Concurrent treatment for chlamydial infection also is indicated.

Workowski KA et al. Emerging antimicrobial resistance in *Neisseria gonorrhoeae*: urgent need to strengthen prevention strategies. Ann Intern Med. 2008 Apr 15;148(8):606–13. [PMID: 18413622]

Workowski KA et al; Centers for Disease Control and Prevention. Sexually transmitted diseases treatment guidelines, 2006. MMWR Recomm Rep. 2006 Aug 4;55(RR-11):1–94. [PMID: 16888612]

Chancroid

Chancroid is a sexually transmitted disease caused by the short gram-negative bacillus *Haemophilus ducreyi.* The incubation period is 3–5 days. At the site of inoculation, a vesicopustule develops that breaks down to form a painful, soft ulcer with a necrotic base, surrounding erythema, and undermined edges. There may be multiple lesions due to autoinoculation. The adenitis is usually unilateral and consists of tender, matted nodes of moderate size with overlying erythema. These may become fluctuant and rupture spontaneously. With lymph node involvement, fever, chills, and malaise may develop. Balanitis and phimosis are frequent complications in men. Women may have no external signs of infection. The diagnosis is established by culturing a swab of the lesion onto a special medium.

Chancroid must be differentiated from other genital ulcers. The chancre of syphilis is clean and painless, with a hard base. Mixed sexually transmitted disease is very common (including syphilis, herpes simplex, and HIV infection), as is infection of the ulcer with fusiforms, spirochetes, and other organisms.

A single dose of either azithromycin, 1 g orally, or ceftriaxone, 250 mg intramuscularly, is effective treatment. Effective multiple-dose regimens are erythromycin, 500 mg orally four times a day for 7 days, or ciprofloxacin, 500 mg orally twice a day for 3 days.

Mohammed TT et al. Chancroid and human immunodeficiency virus infection–a review. Int J Dermatol. 2008 Jan;47(1):1–8. [PMID: 18173591]

Granuloma Inguinale

Granuloma inguinale is a chronic, relapsing granulomatous anogenital infection due to *Calymmatobacterium (Donovania) granulomatis*. The pathognomonic cell, found in tissue scrapings or secretions, is large (25–90 mcm) and contains intracytoplasmic cysts filled with bodies (Donovan bodies) that stain deeply with Wright stain.

The incubation period is 8 days to 12 weeks. The onset is insidious. The lesions occur on the skin or mucous membranes of the genitalia or perineal area. They are relatively painless infiltrated nodules that soon slough. A shallow, sharply demarcated ulcer forms, with a beefy-red friable base of granulation tissue. The lesion spreads by contiguity. The advancing border has a characteristic rolled edge of granulation tissue. Large ulcerations may advance onto the lower abdomen and thighs. Scar formation and healing occur along one border while the opposite border advances.

Superinfection with spirochete-fusiform organisms is common. The ulcer then becomes purulent, painful, foul-smelling, and extremely difficult to treat.

Several therapies are available. Because of the indolent nature of the disease, duration of therapy is relatively long. The following recommended regimens should be given for 3 weeks or until all lesions have healed: doxycycline, 100 mg orally twice daily; or azithromycin, 1 g orally once weekly; or ciprofloxacin, 750 mg orally twice daily; or erythromycin, 500 mg orally four times a day.

Bartonella Species

Bartonella species are responsible for a wide variety of clinical syndromes. **Bacillary angiomatosis**, an important manifestation of bartonellosis, is discussed in Chapter 31: HIV Infection & AIDS A variety of atypical infections, including retinitis, encephalitis, osteomyelitis, and persistent bacteremia and endocarditis have been described..

Trench fever is a self-limited, louse-borne relapsing febrile disease caused by *B quintana*. The disease has occurred epidemically in louse-infested troops and civilians during wars and endemically in residents of scattered geographic areas (eg, Central America). An urban equivalent of trench fever has been described among the homeless. Humans acquire infection when infected lice feces enter sites of skin breakdown. Onset of symptoms is abrupt and fever lasts 3–5 days, with relapses. The patient complains of weakness and severe pain behind the eyes and typically in the back and legs. Lymphadenopathy, splenomegaly, and a transient maculopapular rash may appear. Subclinical infection is frequent, and a carrier state is recognized. The differential diagnosis includes other febrile, self-limited states such as dengue, leptospirosis, malaria, relapsing fever, and typhus. Recovery occurs regularly even in the absence of treatment.

Cat-scratch disease is an acute infection of children and young adults caused by *Bartonella henselae*. It is transmitted from cats to humans as the result of a scratch or bite. Within a few days, a papule or ulcer will develop at the inoculation site in one-third of patients. One to 3 weeks later, fever, headache, and malaise occur. Regional lymph nodes become enlarged, often tender, and may suppurate. Lymphadenopathy from cat scratches resembles that due to neoplasm, tuberculosis, lymphogranuloma venereum, and bacterial lymphadenitis. The diagnosis is usually made clinically. Special cultures for bartonellae, serology, or excisional biopsy, though rarely necessary, confirm the diagnosis. The biopsy reveals necrotizing lymphadenitis and is itself not specific for cat-scratch disease. Cat-scratch disease is usually self-limited, requiring no specific therapy. Encephalitis occurs rarely.

Disseminated forms of the disease—bacillary angiomatosis, peliosis hepatis, and retinitis—occur in HIV-infected persons. The lesions are vasculoproliferative and histopathologically distinct from those of cat-scratch disease. Unexplained fever in patients with late stages of HIV infection is not uncommonly due to bartonellosis. *B quintana*, the agent of trench fever, can also cause bacillary angiomatosis and persistent bacteremia or endocarditis (which will be "culture-negative" unless specifically sought), the latter two entities being associated with homelessness. Due to the fastidious nature of the organism and its special growth requirements, serologic testing (eg, demonstration of a high antibody titer in an indirect immunofluorescence assay) or nucleic acid amplification tests are often required to establish a diagnosis.

Bacillary angiomatosis responds to treatment with a macrolide or doxycycline administered in standard doses for 4–8 weeks. Bacteremia and endocarditis can be effectively treated with a 6-week course of doxycycline (200 mg orally or intravenously in two divided doses per day) plus gentamicin 3 mg/kg/d intravenously for the first 2 weeks. Relapse may occur.

Anaerobic Infections

Anaerobic bacteria comprise the majority of normal human flora. Normal microbial flora of the mouth (anaerobic spirochetes, prevotella, fusobacteria), the skin (anaerobic diphtheroids), the large bowel (bacteroides, anaerobic streptococci, clostridia), and the female genitourinary tract (bacteroides, anaerobic streptococci, fusobacteria) produce disease when displaced from their normal sites into tissues or closed body spaces.

Anaerobic infections tend to be polymicrobial and abscesses are common. Pus and infected tissue often are malodorous. Septic thrombophlebitis and metastatic infection are frequent and may require incision and drainage. Diminished blood supply that favors proliferation of anaerobes because of reduced tissue oxygenation may interfere with the delivery of antimicrobials to the site of anaerobic infection. Cultures, unless carefully collected under anaerobic conditions, may yield negative results.

Important types of infections that are most commonly caused by anaerobic organisms are listed below. Treatment of all these infections consists of surgical exploration and judicious excision in conjunction with administration of antimicrobial drugs.

Head & Neck Infections

Prevotella melaninogenica (formerly *Bacteroides melaninogenicus*) and anaerobic spirochetes are commonly involved in periodontal infections. These organisms, fusobacteria, and peptostreptococci may cause chronic sinusitis, peritonsillar abscess, chronic otitis media, and mastoiditis. Hygiene, drainage, and surgical debridement are as important in treatment as antimicrobials. Oral anaerobic organisms have been uniformly susceptible to penicillin, but there has been a recent trend of increasing penicillin resistance, usually due to -lactamase production. Penicillin, 1–2 million units intravenously every 4 hours (if parenteral therapy is required) or 0.5 g orally four times daily for less severe infections, or clindamycin can be used (600 mg intravenously every 8 hours or 300 mg orally every 6 hours). Antimicrobial treatment is continued for a few days after signs and symptoms of infection have resolved. Indolent, established infections (eg, mastoiditis or osteomyelitis) may require prolonged courses of therapy, eg, 4–6 weeks or longer.

Chest Infections

Usually in the setting of poor oral hygiene and periodontal disease, aspiration of saliva (which contains 10^8 anaerobic organisms per milliliter in addition to aerobes) may lead to necrotizing pneumonia, lung abscess, and empyema. Polymicrobial infection is the rule and anaerobes—particularly *P melaninogenica*, fusobacteria, and peptostreptococci—are common etiologic agents. Septic internal jugular thrombophlebitis (Lemierre syndrome) may originate from mouth anaerobes, classically *Fusobacterium necrophorum*, and cause septic pulmonary embolization. Severe sore throat is a concomitant symptom. Most pulmonary infections respond to antimicrobial therapy alone. Percutaneous chest tube or surgical drainage is indicated for empyema.

Penicillin-resistant *Bacteroides fragilis* and *P melaninogenica* are commonly isolated and have been associated with clinical failures. Clindamycin, 600 mg intravenously once, followed by 300 mg orally every 6–8 hours, is the treatment of choice for these infections. Metronidazole does not cover facultative streptococci, which often are present, and if used, a second agent that is active against streptococci, such as ceftriaxone 1 g intravenously or intramuscularly daily, should be added. Penicillin, 2 million units intravenously every 4 hours, followed by amoxicillin, 500 mg every 8 hours orally, is an alternative; however, increasing prevalence of -lactamase producing organisms is a concern. Moxifloxacin, 400 mg orally or intravenously once daily, may be used. Because these infections respond slowly, a prolonged course of therapy (eg, 4–6 weeks) is generally recommended.

Bartlett JG. The role of anaerobic bacteria in lung abscess. Clin Infect Dis. 2005 Apr 1;40(7):923–5. [PMID: 15824980]

Central Nervous System

Anaerobes are a common cause of brain abscess, subdural empyema, or septic central nervous system thrombophlebitis. The organisms reach the central nervous system by direct extension from sinusitis, otitis, or mastoiditis or by hematogenous spread from chronic lung infections. Antimicrobial therapy—eg, ceftriaxone, 2 g intravenously every 12 hours, plus metronidazole, 750 mg intravenously every 8 hours—is an important adjunct to surgical drainage. Duration of therapy is 6–8 weeks. Some small multiple brain abscesses can be treated with antibiotics alone without surgical drainage.

Menon S et al. Current epidemiology of intracranial abscesses: a prospective 5 year study. J Med Microbiol. 2008 Oct;57(Pt 10):1259–68. [PMID: 18809555]

Intra-abdominal Infections

In the colon there are up to 10^{11} anaerobes per gram of content—predominantly *B fragilis*, clostridia, and peptostreptococci. These organisms play a central role in most intra-abdominal abscesses following trauma to the colon, diverticulitis, appendicitis, or perirectal abscess and may also participate in hepatic abscess and cholecystitis, often in association with aerobic coliform bacteria. The bacteriology includes anaerobes as well as enteric gram-negative rods and on occasion enterococci. Therapy should be directed both against anaerobes and gram-negative aerobes. Agents that are active against *B fragilis* include metronidazole, chloramphenicol, moxifloxacin, tigecycline, ertapenem, imipenem, doripenem, ampicillin-sulbactam, ticarcillin-clavulanic acid, and piperacillin-tazobactam. Resistance to cefoxitin, cefotetan, and clindamycin is increasingly encountered. Most third-generation cephalosporins have poor efficacy. Non-fragilis species of bacteroides may be less susceptible to the cephalosporins.

Table 33–6 summarizes the antibiotic regimens for management of moderate to moderately severe infections (eg, patient hemodynamically stable, good surgical drainage possible or established, low APACHE score, no multiple organ failure) and severe infections (eg, major peritoneal soilage, large or multiple abscesses, patient hemodynamically unstable), particularly if drug-resistant organisms are suspected. An effective oral regimen for patients able to take it is presented also.

Table 33–6. Treatment of anaerobic intra-abdominal infections.
Oral therapy
Moxifloxacin 400 mg every 24 hours
Intravenous therapy
Moderate to moderately severe infections:
Ertapenem 1 g every 24 hours
or—
Ceftriaxone 1 g every 24 hours (or ciprofloxacin 400 mg every 12 hours, if penicillin allergic) plus metronidazole 500 mg every 8 hours
or—
Tigecycline 100 mg once followed by 50 mg every 12 hours
or—
Moxifloxacin 400 mg every 24 hours
Severe infections:
Imipenem, 0.5 g every 6–8 hours; meropenem 1 g every 8 hours; doripenem 0.5 g every 8 hours; piperacillin/tazobactam 3.375 g every 6 hours

Brook I. Treatment of anaerobic infection. Expert Rev Anti Infect Ther. 2007 Dec;5(6):991–1006. [PMID:

18039083]

Female Genital Tract & Pelvic Infections

The normal flora of the vagina and cervix includes several species of bacteroides, peptostreptococci, group B streptococci, lactobacilli, coliform bacteria, and, occasionally, spirochetes and clostridia. These organisms commonly cause genital tract infections and may disseminate from there.

While salpingitis is often caused by gonococci and chlamydiae, tubo-ovarian and pelvic abscesses are associated with anaerobes in most cases. Postpartum infections may be caused by aerobic streptococci or staphylococci, but anaerobes are often found, and the worst cases of postpartum or postabortion sepsis are associated with clostridia and bacteroides. These have a high mortality rate, and treatment requires both antimicrobials directed against anaerobes and coliforms (see above) and abscess drainage or early hysterectomy.

Trigg BG et al. Sexually transmitted infections and pelvic inflammatory disease in women. Med Clin North Am. 2008 Sep;92(5):1083–113. [PMID: 18721654]

Bacteremia & Endocarditis

Anaerobic bacteremia usually originates from the gastrointestinal tract, the oropharynx, decubitus ulcers, or the female genital tract. Endocarditis due to anaerobic and microaerophilic streptococci and bacteroides originates from the same sites. Most cases of anaerobic or microaerophilic streptococcal endocarditis can be effectively treated with 12–20 million units of penicillin G daily for 4–6 weeks, but optimal therapy of other types of anaerobic bacterial endocarditis must rely on laboratory guidance. Anaerobic corynebacteria (propionibacteria), clostridia, and bacteroides occasionally cause endocarditis.

Skin & Soft Tissue Infections

Anaerobic infections in the skin and soft tissue usually follow trauma, inadequate blood supply, or surgery and are most common in areas that are contaminated by oral or fecal flora. These infections also occur in injection drug users and persons sustaining animal to human bites. There may be progressive tissue necrosis (Plate 104) and a putrid odor.

Plate 104.

Gangrene of the right foot causing necrosis of the toes. (Courtesy of William Archibald, Public Health Image

Library, CDC.)

Several terms, such as bacterial synergistic gangrene, synergistic necrotizing cellulitis, necrotizing fasciitis, and nonclostridial crepitant cellulitis, have been used to classify these infections. Although there are some differences in microbiology among them, their differentiation on clinical grounds alone is difficult. All are mixed infections caused by aerobic and anaerobic organisms and require aggressive surgical debridement of necrotic tissue for cure. Surgical consultation is obligatory to assist in diagnosis and treatment.

Broad-spectrum antibiotics active against both anaerobes and gram-positive and gram-negative aerobes (eg, vancomycin plus piperacillin-tazobactam) should be instituted empirically and modified by culture results (Table 30–9). They are given for about a week after progressive tissue destruction has been controlled and the margins of the wound remain free of inflammation.

Anaya DA et al. Necrotizing soft-tissue infection: diagnosis and management. Clin Infect Dis. 2007 Mar 1;44(5):705–10. [PMID: 17278065]

Actinomycosis

Essentials of Diagnosis

- History of recent dental infection or abdominal

trauma.
- Chronic pneumonia or indolent intra-abdominal or cervicofacial abscess.
- Sinus tract formation.

General Considerations

Actinomyces israelii and other species of *Actinomyces* occur in the normal flora of the mouth and tonsillar crypts. They are anaerobic, gram-positive, branching filamentous bacteria (1 mcm in diameter) that may fragment into bacillary forms. When introduced into traumatized tissue and associated with other anaerobic bacteria, these actinomycetes become pathogens.

The most common site of infection is the cervicofacial area (about 60% of cases). Infection typically follows extraction of a tooth or other trauma. Lesions may develop in the gastrointestinal tract or lungs following ingestion or aspiration of the organism from its endogenous source in the mouth. Interestingly, *T whippelii*, the causative agent of Whipple disease, is an actinomycete and therefore is related to the species that cause actinomycosis.

Clinical Findings

Symptoms and Signs

Cervicofacial Actinomycosis

Cervicofacial actinomycosis develops slowly. The area becomes markedly indurated, and the overlying skin becomes reddish or cyanotic. Abscesses eventually draining to the surface persist for long periods. Sulfur granules—masses of filamentous organisms—may be found in the pus. There is usually little pain unless there is secondary infection. Trismus indicates that the muscles of mastication are involved. Radiography may reveal bony involvement.

Thoracic Actinomycosis

Thoracic involvement begins with fever, cough, and sputum production with night sweats and weight loss. Pleuritic pain may be present. Multiple sinuses may extend through the chest wall, to the heart, or into the abdominal cavity. Ribs may be involved. Radiography shows areas of consolidation and in many cases pleural effusion. Cervicofacial or thoracic disease may occasionally involve the central nervous system, most commonly brain abscess or meningitis.

Abdominal Actinomycosis

Abdominal actinomycosis usually causes pain in the ileocecal region, spiking fever and chills, vomiting, and weight loss; it may be confused with Crohn disease. Irregular abdominal masses may be palpated. Pelvic inflammatory disease caused by actinomycetes has been associated with prolonged use of an intrauterine contraceptive device. Sinuses draining to the exterior may develop. CT scanning reveals an inflammatory mass extended to involve bone.

Laboratory Findings

The anaerobic, gram-positive organism may be demonstrated as a granule or as scattered branching gram-positive filaments in the pus. Anaerobic culture is necessary to distinguish actinomycetes from nocardiae because specific therapy differs for the two infections.

Treatment

With penicillin and surgery, the prognosis is good. The difficulties of diagnosis, however, may permit extensive destruction of tissue before the diagnosis is identified and therapy is started.

Sharkawy AA. Cervicofacial actinomycosis and mandibular osteomyelitis. Infect Dis Clin North Am. 2007 Jun;21(2):543–56. [PMID: 17561082]

Nocardiosis

Nocardia asteroides, an aerobic filamentous soil bacterium, causes pulmonary and systemic nocardiosis. Bronchopulmonary abnormalities (eg, alveolar proteinosis) predispose to colonization, but infection is unusual unless the patient is also receiving systemic corticosteroids or is otherwise immunosuppressed.

Pulmonary involvement usually begins with malaise, loss of weight, fever, and night sweats. Cough and production of purulent sputum are the chief complaints. Radiography may show infiltrates accompanied by pleural effusion. The lesions may penetrate to the exterior through the chest wall, invading the ribs.

Dissemination involves any organ. Brain abscesses and subcutaneous nodules are most frequent. This is seen exclusively in immunocompromised patients.

N asteroides is usually found as delicate, branching, gram-positive filaments. It may be weakly acid-fast, occasionally causing diagnostic confusion with tuberculosis. Identification is made by culture.

For cutaneous infections, therapy is initiated with intravenous trimethoprim-sulfamethoxazole administered at a dosage of 5–10 mg/kg/d (based on trimethoprim) and continued with oral trimethoprim-sulfamethoxazole, one double-strength tablet twice a day. Surgical procedures such as drainage and resection may be needed as adjunctive therapy. A higher dose of 15 mg/kg/d (based on trimethoprim) should be used for disseminated or pulmonary infections. Imipenem 500 mg intravenously every 6 hours is an alternative.

Response may be slow, and therapy must be continued for at least 6 months. The prognosis in systemic nocardiosis is poor when diagnosis and therapy are delayed.

Nocardia brasiliensis typically causes a digital lesion—resembling herpetic whitlow—and ascending lymphangitis in normal hosts. Antimicrobial treatment is as for *N asteroides* infection, and the prognosis is excellent.

Martínez R et al. Pulmonary nocardiosis: risk factors, clinical features, diagnosis and prognosis. Curr Opin Pulm Med. 2008 May;14(3):219–27. [PMID: 18427245]

Peleg AY et al. Risk factors, clinical characteristics, and outcome of *Nocardia* infection in organ transplant recipients: a matched case-control study. Clin Infect Dis. 2007 May 15;44(10):1307–14. [PMID: 17443467]

Nontuberculous Atypical Mycobacterial Diseases

About 10% of mycobacterial infections are caused by atypical mycobacteria. Atypical mycobacterial infections are among the most common opportunistic infections in advanced HIV disease. These organisms have distinctive laboratory characteristics, occur ubiquitously in the environment, are not communicable from person to person, and are often resistant to standard antituberculous drugs.

Disseminated *Mycobacterium avium* Infection

Mycobacterium avium complex (MAC) produces asymptomatic colonization or a wide spectrum of diseases, including coin lesions, bronchitis in patients with chronic lung disease, and invasive pulmonary disease that is often cavitary and occurs in patients with underlying lung disease. MAC causes disseminated disease in the late stages of HIV infection, when the CD4 cell count is less than 50/mcL. Persistent fever and weight loss are the most common symptoms. The organism can usually be cultured from multiple sites, including blood, liver, lymph node, or bone marrow. Blood culture is the preferred means of establishing the diagnosis and has a sensitivity of 98%.

Agents with proved activity against MAC are rifabutin, azithromycin, clarithromycin, and ethambutol. Amikacin and ciprofloxacin work in vitro, but clinical results are inconsistent. A combination of two or more active agents should be used to prevent rapid emergence of secondary resistance. Clarithromycin, 500 mg orally twice daily, plus ethambutol, 15 mg/kg/d orally as a single dose, with or without rifabutin, 300 mg/d orally, is the treatment of choice. Azithromycin, 500 mg orally once daily, may be used instead of clarithromycin. Insufficient data are available to permit specific recommendations about second-line regimens for patients intolerant of macrolides or those with macrolide-resistant organisms. MAC therapy may be discontinued in patients who have been treated with 12 months of therapy for disseminated MAC, who have no evidence of active disease, and whose CD4 counts exceed 100 cells/mcL while receiving highly active antiretroviral therapy (HAART). Antimicrobial prophylaxis of MAC prevents disseminated disease and prolongs survival. It is the standard of care to offer it to all HIV-infected patients with CD4 counts 50/mcL. In contrast to active infection, single-drug oral regimens of clarithromycin, 500 mg twice daily, azithromycin, 1200 mg once weekly, or rifabutin, 300 mg once daily, are appropriate. Clarithromycin or azithromycin is more effective and better tolerated than rifabutin, and therefore preferred. Primary prophylaxis for MAC infection can be stopped in patients who have responded to antiretroviral combination therapy with elevation of CD4 counts above 100 cells/mcL for 3 months.

Pulmonary Infections

MAC causes a chronic, slowly progressive pulmonary infection resembling tuberculosis in immunocompetent patients, who typically have underlying pulmonary disease.

Treatment of immunocompetent patients with pulmonary infection is empiric and based entirely on anecdotal data. A combination of agents is probably best. Rifampin, 600 mg orally once daily, plus ethambutol, 15–25 mg/kg/d orally, plus streptomycin, 1 g intramuscularly three to five times a week for the first 4–6 months, have been used. The role of rifabutin, fluoroquinolones, and the macrolides is not known, but based on their excellent efficacy in immunocompromised AIDS patients, they may actually be more effective than the relatively weak agents traditionally used in immunocompetent patients. Clarithromycin is a very potent drug in the treatment of MAC in AIDS patients. Based on this, inclusion of clarithromycin in the initial treatment regimen of immunocompetent patients is prudent. Therapy is continued for a total of 18–24 months.

Mycobacterium kansasii can produce clinical disease resembling tuberculosis, but the illness progresses more slowly. Most such infections occur in patients with preexisting lung disease, though 40% of patients have no known pulmonary disease. Microbiologically, *M kansasii* is similar to *Mycobacterium tuberculosis* and is sensitive to the same drugs except pyrazinamide, to which it is resistant. Therapy with isoniazid, ethambutol, and rifampin for 2 years (or 1 year after sputum conversion) has been successful.

Less common causes of pulmonary disease include *Mycobacterium xenopi*, *Mycobacterium szulgai*, and *Mycobacterium gordonae.* These organisms have variable sensitivities, and treatment is based on results of sensitivity tests. The rapid growing mycobacteria, *Mycobacterium abscessus, Mycobacterium chelonae,* and *Mycobacterium fortuitum* also can cause pneumonia in the occasional patient.

Lymphadenitis

Most cases of lymphadenitis (scrofula) in adults are caused by *M tuberculosis* and can be a manifestation of disseminated disease. In children, the majority of cases are due to nontuberculous mycobacterial species, with MAC being the most common followed by *Mycobacterium scrofulaceum* in the United States and *Mycobacterium malmoense* and *Mycobacterium haemophilum* in Northern Europe. *M kansasii, Mycobacterium bovis, M chelonae*, and *M fortuitum* are less commonly observed. Unlike disease caused by *M tuberculosis*, which requires systemic therapy for 6 months, infection with nontuberculous mycobacteria can be successfully treated by surgical excision without antituberculous therapy.

Skin & Soft Tissue Infections

Skin and soft tissue infections such as abscesses, septic arthritis, and osteomyelitis can result from direct inoculation or hematogenous dissemination or may occur as a complication of surgery.

M abscessus, M chelonae, and *M fortuitum* are frequent causes of this type of infection. Most cases occur in the extremities and initially present as nodules. Ulceration with abscess formation often follows. The organisms are resistant to the usual antituberculous drugs but may be sensitive to a variety of antibiotics, including erythromycin, doxycycline, amikacin, cefoxitin, sulfonamides, imipenem, and ciprofloxacin. Therapy includes surgical debridement along with drug therapy. Initially, parenteral drugs are given for several weeks, and this is followed by an oral regimen to which the organism is sensitive. The duration of therapy is variable but usually continues for several months after the soft tissue lesions have healed.

Mycobacterium marinum infection ("swimming pool granuloma") presents as a nodular skin lesion following exposure to nonchlorinated water. The lesions respond to therapy with clarithromycin, doxycycline, minocycline, or trimethoprim-sulfamethoxazole.

Mycobacterium ulcerans infection (Buruli ulcer) is seen mainly in Africa and Australia and produces a large ulcerative lesion. Therapy consists of surgical excision and skin grafting.

Mycobacterium Tuberculosis Infections

Tuberculosis is discussed in Chapter 9: Pulmonary Disorders. Further information and expert consultation can be obtained from the Francis J. Curry National Tuberculosis Center at the Web site http://www.nationaltbcenter.edu or, by phone, 415-502-4600, or fax, 415-502-4620.

Tuberculous Meningitis

Essentials of Diagnosis

- Gradual onset of listlessness, irritability, and anorexia.
- Headache, vomiting, and seizures common.
- Cranial nerve abnormalities typical.
- Tuberculosis focus may be evident elsewhere.
- Cerebrospinal fluid shows several hundred

lymphocytes, low glucose, and high protein.

General Considerations

Tuberculous meningitis is caused by rupture of a meningeal tuberculoma resulting from earlier hematogenous seeding of tubercle bacilli from a pulmonary focus, or it may be a consequence of miliary spread.

Clinical Findings

Symptoms and Signs

The onset is usually gradual, with listlessness, irritability, anorexia, and fever, followed by headache, vomiting, convulsions, and coma. In older patients, headache and behavioral changes are prominent early symptoms. Nuchal rigidity and cranial nerve palsies occur as the meningitis progresses. Evidence of active tuberculosis elsewhere or a history of prior tuberculosis is present in up to 75% of patients.

Laboratory Findings

The spinal fluid is frequently yellowish, with increased pressure, 100–500 cells/mcL (predominantly lymphocytes, though neutrophils may be present early during infection), increased protein, and decreased glucose. Acid-fast stains of cerebrospinal fluid usually are negative, and cultures also may be negative in 15–25% of cases. Nucleic acid amplification tests for rapid diagnosis of tuberculosis have variable sensitivity and specificity and none are FDA-approved for use in meningitis. Chest x-ray often reveals abnormalities compatible with tuberculosis but may be normal.

Differential Diagnosis

Tuberculous meningitis may be confused with any other type of meningitis, but the gradual onset, the predominantly lymphocytic pleocytosis of the spinal fluid, and evidence of tuberculosis elsewhere often point to the diagnosis. The tuberculin skin test is usually (not always) positive. Fungal and other granulomatous meningitides, syphilis, and carcinomatous meningitis are in the differential diagnosis.

Complications

Complications of tuberculous meningitis include seizure disorders, cranial nerve palsies, stroke, and obstructive hydrocephalus with impaired cognitive function. These result from inflammatory exudate primarily involving the basilar meninges and arteries.

Treatment

Presumptive diagnosis followed by early, empiric antituberculous therapy is essential for survival and to minimize sequelae. Even if cultures are not positive, a full course of therapy is warranted if the clinical setting is suggestive of tuberculous meningitis.

Regimens that are effective for pulmonary tuberculosis are effective also for tuberculous meningitis (see Table 9–13). Rifampin, isoniazid, and pyrazinamide all penetrate into cerebrospinal fluid well. The penetration of ethambutol is more variable, but therapeutic concentrations can be achieved, and the drug has been successfully used for meningitis. Aminoglycosides penetrate less well. Regimens that do not include both isoniazid and rifampin may be effective but are less reliable and generally must be given for longer periods.

Many authorities recommend the addition of corticosteroids for patients with focal deficits or altered mental status. Dexamethasone, 0.15 mg/kg intravenously or orally four times daily for 1–2 weeks, then discontinued in a tapering regimen over 4 weeks, may be used.

Leprosy (Hansen Disease)

Essentials of Diagnosis

- Pale, anesthetic macular—or nodular and erythematous—skin lesions.
- Superficial nerve thickening with associated anesthesia.
- History of residence in endemic area in childhood.
- Acid-fast bacilli in skin lesions or nasal scrapings, or characteristic histologic nerve changes.

General Considerations

Leprosy (Hansen disease) is a chronic infectious disease caused by the acid-fast rod *Mycobacterium leprae.* The mode of transmission probably is respiratory and involves prolonged exposure in childhood. The disease is endemic in tropical and subtropical Asia, Africa, Central and South America, and the Pacific regions, and rarely seen sporadically in the southern United States.

Clinical Findings

Symptoms and Signs

The onset is insidious. The lesions involve the cooler body tissues: skin, superficial nerves, nose, pharynx, larynx, eyes, and testicles. Skin lesions may occur as pale, anesthetic macular lesions 1–10 cm in diameter; discrete erythematous, infiltrated nodules 1–5 cm in diameter; or diffuse skin infiltration. Neurologic disturbances are caused by nerve infiltration and thickening, with resultant anesthesia, and motor abnormalities. Bilateral ulnar neuropathy is highly suggestive. In untreated cases, disfigurement due to the skin infiltration and nerve involvement may be extreme, leading to trophic ulcers, bone resorption, and loss of digits.

The disease is divided clinically and by laboratory tests into two distinct types: lepromatous and tuberculoid. The **lepromatous** type (also referred to as multibacillary leprosy) occurs in persons with defective cellular immunity. The course is progressive and malignant, with nodular skin lesions; slow, symmetric nerve involvement; abundant acid-fast bacilli in the skin lesions; and a negative lepromin skin test. In the **tuberculoid** type (paucibacillary leprosy), cellular immunity is intact and the course is more benign and less progressive, with macular skin lesions, severe asymmetric nerve involvement of sudden onset with few bacilli present in the lesions, and a positive lepromin skin test. Intermediate ("borderline") cases are frequent. Eye involvement (keratitis and iridocyclitis), nasal ulcers, epistaxis, anemia, and lymphadenopathy may occur.

Laboratory Findings

Laboratory confirmation of leprosy requires the demonstration of acid-fast bacilli in a skin biopsy. Biopsy of skin or of a thickened involved nerve also gives a typical histologic picture. *M leprae* does not grow in artificial media but does grow in the foot pads of armadillos.

Differential Diagnosis

The skin lesions of leprosy often resemble those of lupus erythematosus, sarcoidosis, syphilis, erythema nodosum, erythema multiforme, cutaneous tuberculosis, and vitiligo.

Complications

Kidney failure and hepatomegaly from secondary amyloidosis may occur with longstanding disease.

Treatment

Combination therapy is recommended for treatment of all types of leprosy. Single-drug treatment is accompanied by emergence of resistance, and primary resistance to dapsone also occurs. For borderline and lepromatous cases (ie, multibacillary disease), the World Health

Organization recommends a triple drug-regimen of rifampin, 600 mg once a month; dapsone, 100 mg daily; and clofazimine, 300 mg once a month and 50 mg daily for 12 months. For indeterminate and tuberculoid leprosy (paucibacillary disease), the recommendation is rifampin, 600 mg once a month, plus dapsone, 100 mg daily for 6 months.

Two reactional states—erythema nodosum leprosum and reversal reactions—may occur as a consequence of therapy. The reversal reaction, typical of borderline lepromatous leprosy, probably results from enhanced host immunity. Skin lesions and nerves become swollen and tender, but systemic manifestations are not seen. Erythema nodosum leprosum, typical of lepromatous leprosy, is a consequence of immune injury from antigen-antibody complex deposition in skin and other tissues; in addition to skin and nerve manifestations, fever and systemic involvement may be seen. Prednisone, 60 mg/d orally, or thalidomide, 300 mg/d orally (in the nonpregnant patient only), is effective for erythema nodosum leprosum. Improvement is expected within a few days after initiating prednisone, and thereafter the dose may be tapered over several weeks to avoid recurrence. Thalidomide is also tapered over several weeks to a 100-mg bedtime dose. Erythema nodosum leprosum is usually confined to the first year of therapy, and prednisone or thalidomide can be discontinued.

Thalidomide is ineffective for reversal reactions, and prednisone, 60 mg/d, is indicated. Reversal reactions tend to recur, and the dose of prednisone should be slowly tapered over weeks to months. Therapy for leprosy should not be discontinued during treatment of reactional states.

Chlamydiae: Introduction

Chlamydiaceae is a family of obligate intracellular parasites closely related to gram-negative bacteria. They include two important genera of human pathogens — *Chlamydia*, which includes the species *Chlamydia trachomatis*, and *Chlamydophila*, which include the species *Chlamydophila psittaci* (formerly known as *Chlamydia psittaci*) and *Chlamydophila pneumoniae* (formerly known as *Chlamydia pneumoniae*). The differentiation of genera is based on differences in intracellular inclusions, sulfonamide susceptibility, antigenic composition, and disease production. *C trachomatis* causes many different human infections involving the eye (trachoma, inclusion conjunctivitis), the genital tract (lymphogranuloma venereum, nongonococcal urethritis, cervicitis, salpingitis), or the respiratory tract in infants (pneumonitis). *C psittaci* causes psittacosis and *C pneumoniae* is a cause of respiratory tract infections.

See Related Guideline from *CURRENT Practice Guidelines in Primary Care 2009*
Chlamydia Trachomatis Infections

Lymphogranuloma Venereum

Essentials of Diagnosis

- Evanescent primary genital lesion.
- Lymph node enlargement, softening, and suppuration, with draining sinuses.
- Proctitis and rectal stricture in women or homosexual men.
- Positive complement fixation test.

General Considerations

Lymphogranuloma venereum (LGV) is an acute and chronic sexually transmitted disease caused by *C trachomatis* types L1–L3. The disease is acquired during intercourse or through contact with contaminated exudate from active lesions. The incubation period is 5–21 days. After the genital lesion disappears, the infection spreads to lymph channels and lymph nodes of the genital and rectal areas. Inapparent infections and latent disease are not uncommon.

Clinical Findings

Symptoms and Signs

In men, the initial vesicular or ulcerative lesion (on the external genitalia) is evanescent and often goes unnoticed. Inguinal buboes appear 1–4 weeks after exposure, are often bilateral, and have a tendency to fuse, soften, and break down to form multiple draining sinuses, with extensive scarring. In women, the genital lymph drainage is to the perirectal glands. Early anorectal manifestations are proctitis with tenesmus and bloody purulent discharge; late manifestations are chronic cicatrizing inflammation of the rectal and perirectal tissue. These changes lead to obstipation and rectal stricture and, occasionally, rectovaginal and perianal fistulas. They are also seen in homosexual men.

Laboratory Findings

The complement fixation test may be positive (titers > 1:64), but cross-reaction with other chlamydiae occurs. Although a positive reaction may reflect remote infection, high titers usually indicate active disease. Nucleic acid detection tests are sensitive, but not FDA-approved for rectal specimens and cannot differentiate LGV from non-LGV strains.

Differential Diagnosis

The early lesion of LGV must be differentiated from the lesions of syphilis, genital herpes, and chancroid; lymph node involvement must be distinguished from that due to tularemia, tuberculosis, plague, neoplasm, or pyogenic infection; and rectal stricture must be distinguished from that due to neoplasm and ulcerative colitis.

Treatment

If diagnostic testing for LGV is not available, patients with a clinical presentation suggestive of LGV should be treated empirically. The antibiotic of choice is doxycycline (contraindicated in pregnancy), 100 mg orally twice daily for 21 days. Erythromycin, 500 mg orally four times a day for 21 days, is also effective. Azithromycin, 1 g orally once weekly for 3 weeks, may also be effective.

McLean CA et al. Treatment of lymphogranuloma venereum. Clin Infect Dis. 2007 Apr 1;44 (Suppl 3):S147–52. [PMID: 17342667]

Chlamydial Urethritis & Cervicitis

C trachomatis immunotypes D–K are isolated in about 50% of cases of nongonococcal urethritis and cervicitis by appropriate techniques. In other cases, *Ureaplasma urealyticum* and *Mycoplasma genitalium* can be grown as a possible etiologic agent. *C trachomatis* is an important cause of postgonococcal urethritis. Coinfection with gonococci and chlamydiae is common, and postgonococcal (ie, chlamydial) urethritis may persist after successful treatment of the gonococcal component. Occasionally, epididymitis, prostatitis, or proctitis is caused by chlamydial infection.

Females infected with chlamydiae may be asymptomatic or may have symptoms and signs of cervicitis, salpingitis, or pelvic inflammatory disease. Chlamydiae are a leading cause of infertility in females in the United States. Active screening for chlamydial infection is recommended in certain settings: pregnant women; all sexually active women 25 years of age and under; older women with risk factors for sexually transmitted diseases; and men with risk factors for sexually transmitted diseases, such as HIV-positive men or men who have sex with men.

The urethral or cervical discharge due to *C trachomatis* tends to be less painful, less purulent, and watery compared with gonococcal infection. A patient with urethritis or cervicitis and absence of gram-negative diplococci on Gram stain and of *N gonorrhoeae* on culture is assumed to have chlamydial infection until proven otherwise. In the past, the diagnosis of chlamydial infection has been clinical because *C trachomatis* is difficult and expensive to culture; therefore, therapy often was given presumptively. The advent of FDA-approved, highly sensitive nucleic acid amplification tests for use with urine or vaginal swabs has simplified matters, and the diagnosis should be confirmed whenever possible. A negative nucleic acid amplification test for chlamydia reliably excludes the diagnosis of chlamydial urethritis or cervicitis and therapy need not be administered. Presumptively administered therapy still may be indicated in some cases (such as for an individual with gonococcal infection in whom no chlamydial testing was performed or a test other than a nucleic acid amplification test was used to exclude the diagnosis, an individual for whom a test result is pending but is considered unlikely to follow-up, and for sexual contacts of documented cases).

Recommended regimens are a single oral 1-g dose of azithromycin (preferred and safe in pregnancy), 100 mg of doxycycline orally for 7 days (contraindicated in pregnancy), or 500 mg of levofloxacin once daily for 7 days (also contraindicated in pregnancy). As for all sexually transmitted diseases, studies for HIV and syphilis should be performed.

Chlamydia psittaci & Psittacosis (Ornithosis)

Essentials of Diagnosis

- Fever, chills, and cough; headache common.
- Atypical pneumonia with slightly delayed appearance of signs of pneumonitis.
- Contact with infected bird (psittacine, pigeons, many others) 7–15 days previously.
- Isolation of chlamydiae or rising titer of complement-fixing antibodies.

General Considerations

Psittacosis is acquired from contact with birds (parrots, parakeets, pigeons, chickens, ducks, and many others), which may or may not be ill. The history may be difficult to obtain if the patient acquired infection from an illegally imported bird.

Clinical Findings

The onset is usually rapid, with fever, chills, myalgia, dry cough, and headache. Signs include temperature-pulse dissociation, dullness to percussion, and rales. Pulmonary findings may be absent early. Dyspnea and cyanosis may occur later. Endocarditis, which is culture-negative, may occur. The radiographic findings in typical psittacosis are those of atypical pneumonia, which tends to be interstitial and diffuse in appearance, though consolidation can occur. Psittacosis is indistinguishable from other bacterial or viral pneumonias by radiography.

The organism is rarely isolated from cultures. The diagnosis is usually made serologically; antibodies appear during the second week and can be demonstrated by complement fixation or immunofluorescence. Antibody response may be suppressed by early chemotherapy.

Differential Diagnosis

The illness is indistinguishable from viral, mycoplasmal, or other atypical pneumonias except for the history of contact with birds. Psittacosis is in the differential diagnosis of culture-negative endocarditis.

Treatment

Treatment consists of giving tetracycline, 0.5 g orally every 6 hours or 0.5 g intravenously every 12 hours, for 14–21 days. Erythromycin, 500 mg orally every 6 hours, may be effective as well.

Husain A et al. Meta-analyses of the association between *Chlamydia psittaci* and ocular adnexal lymphoma and the response of ocular adnexal lymphoma to antibiotics. Cancer. 2007 Aug 15;110(4):809–15. [PMID: 17594698]

Chlamydophila Pneumoniae Infection

C pneumoniae causes pneumonia and bronchitis. The clinical presentation of pneumonia is that of an atypical pneumonia. The organism accounts for approximately 10% of community-acquired pneumonias, ranking second to mycoplasma as an agent of atypical pneumonia. A putative role in coronary artery disease has not held up to close scientific scrutiny.

Like *C psittaci*, strains of *C pneumoniae* are resistant to sulfonamides. Erythromycin or tetracycline, 500 mg orally four times a day for 10–14 days, appears to be effective therapy. Fluoroquinolones, such as levofloxacin (500 mg once daily for 7–14 days) or moxifloxacin (400 mg once daily for 7–14 days), are active in vitro against *C pneumoniae* and probably are effective. It is unclear if empiric coverage for atypical pathogens in hospitalized patients with community-acquired pneumonia provides a survival benefit or improves clinical outcome.

Syphilis

Natural History & Principles of Diagnosis & Treatment

Syphilis is a complex infectious disease caused by *Treponema pallidum*, a spirochete capable of infecting almost any organ or tissue in the body and causing protean clinical manifestations (Table 34–1). Transmission occurs most frequently during sexual contact (including oral sex), through minor skin or mucosal lesions; sites of inoculation are usually genital but may be extragenital. The risk of developing syphilis after unprotected sex with an individual with infectious syphilis is approximately 30–50%. Rarely, it can also be transmitted through nonsexual contact, blood transfusion, or via the placenta from mother to fetus (congenital syphilis). The immunologic response to infection is complex, but it provides the basis for most clinical diagnoses. The infection induces the synthesis of a number of antibodies, some of which react specifically with pathogenic treponemes and some with components of normal tissues (see below). If the disease is untreated, in most cases these immune reactions fail to eradicate existing infection and may contribute to tissue degeneration in the late stages. Patients treated early in the disease are fully susceptible to reinfection.

Table 34–1. Stages of syphilis and common clinical manifestations.
Primary syphilis
Genital ulcer: painless ulcer with clean base and firm indurated borders
Regional lymphadenopathy
Secondary syphilis
Skin and mucous membranes
Rash: diffuse (including palms and soles), macular, papular, pustular, and combinations
Condylomata lata
Mucous patches: painless, silvery ulcerations of mucous membrane with surrounding erythema
Generalized lymphadenopathy
Constitutional symptoms
Fever, usually low-grade
Malaise
Anorexia
Arthralgias and myalgias
Central nervous system

Asymptomatic
Symptomatic
Headache
Meningitis
Cranial neuropathies (II–VIII)
Ocular
Iritis
Iridocyclitis
Other
Renal: glomerulonephritis, nephrotic syndrome
Liver: hepatitis
Bone and joint: arthritis, periostitis
Late syphilis
Late benign (gummatous): granulomatous lesion usually involving skin, mucous membranes and bones, but any organ can be involved
Cardiovascular
Aortic regurgitation
Coronary ostial stenosis
Aortic aneurysm
Neurosyphilis
Asymptomatic
Meningovascular

Seizures
Hemiparesis or hemiplegia
Tabes dorsalis
Impaired proprioception and vibratory sensation
Argyll Robertson pupil
Shooting pains
Ataxia
Romberg sign
Urinary and fecal incontinence
Charcot joint
Cranial nerve involvement (II–VIII)
General paresis
Personality changes
Hyperactive reflexes
Argyll Robertson pupil
Decreased memory
Slurred speech
Optic atrophy

The natural history of acquired syphilis is generally divided into two major clinical stages: **early (infectious) syphilis** and **late syphilis**. The two stages are separated by a symptom-free latent phase during the first part of which (early latency) infectious lesions are liable to recur.

Infectious syphilis includes the primary lesions (chancre and regional lymphadenopathy), the secondary lesions (commonly involving skin and mucous membranes, occasionally bone, central nervous system, or liver), relapsing lesions during early latency, and congenital lesions. The hallmark of these lesions is an abundance of spirochetes; tissue reaction is usually minimal. Late syphilis consists of so-called benign (gummatous) lesions involving skin, bones, and viscera; cardiovascular disease (principally aortitis); and a variety of central nervous system and ocular syndromes. These forms of syphilis are not contagious. The lesions contain few demonstrable spirochetes, but tissue reactivity (vasculitis, necrosis) is severe and suggestive of hypersensitivity phenomena.

Public health efforts to control syphilis focus on the diagnosis and treatment of early (infectious) cases and their partners. As a result of these efforts and the introduction of penicillin during and after World War II, there was a reduction in the incidence of infectious syphilis. There was a resurgence of disease in the 1960s and 1970s, but the incidence never reached that of the pre-penicillin era. In the early 1980s, the incidence of infectious syphilis increased, with a particularly high rate among homosexual men. In the mid-1980s, there was a slight decrease, primarily a result of changes in sexual practices in response to the AIDS epidemic. Between 1985 and 1990, there was again a dramatic increase in infectious syphilis, with more than 50,000 cases of primary and secondary syphilis reported in 1990. This increase was broad based, affecting both men and women in inner city, urban, and rural areas, particularly in the southern regions of the United States. Although adolescent and young adult blacks were primarily affected, increases were seen in other ethnic groups also, as well as adults over 60 years of age. Limited access to health care, decreases in health department clinical services, increased use of illicit drugs (especially "crack cocaine"), the exchange of sex for drugs or money to buy drugs, and the difficulty of contact tracing when multiple sexual partners are involved all contributed to the dramatic increase. Concomitantly with the increase in acquired syphilis, there was also an increase in congenital syphilis, particularly in urban areas. In 1998, in response to this increase in infectious syphilis, the United States Congress allocated funds for a syphilis elimination program. This included intensive syphilis control programs targeting high-risk populations (women of childbearing age, sexually active teens, drug users, inmates of penal institutions, persons with multiple sexual partners or those who have sex with prostitutes) emphasizing screening, early treatment, contact tracing, and condom use. The effort was initially successful, as evidenced by a decrease in the number of primary and secondary cases reported in 2000 (5979 cases) compared with 1998 (7035 cases). However, in 2006, the number of cases was 9756, the highest since 1996. These increases occurred mainly among men, suggesting that the increase is likely in the group of men having sex with men (MSM) and is due to multiple factors (including disinhibition with availability of highly active antiretroviral therapy and decreased use of condoms [serosorting]). Most cases of syphilis in the United States continue to occur in MSM. From 2005 to 2006, the number of cases of primary and secondary syphilis was stable among white women and decreased in Hispanic women but increased for black and Hispanic men and black women. Most cases are still reported from the South, but urban outbreaks (New York City, San Francisco) are being reported with increasing frequency. The number of congenital syphilis cases increased slightly, to 8.5 cases/100,000 population in 2006. Despite the increase in primary and secondary syphilis in MSM, in certain urban areas, such as San Francisco, there has not been a concomitant increase in the incidence of HIV.

Course & Prognosis

The lesions associated with primary and secondary syphilis are self-limiting, even without treatment, and resolve with few or no residua. Late syphilis may be highly destructive and permanently disabling and may lead to death. Many experts now believe that while infection is almost never completely eradicated in the absence of treatment, most infections remain latent without sequelae, and only a small number of latent infections progress to further disease.

Clinical Stages of Syphilis

Primary Syphilis

Essentials of Diagnosis

- History of sexual contact (often unreliable).
- Painless ulcer on genitalia, perianal area, rectum, pharynx, tongue, lip, or elsewhere 2–6 weeks after exposure.
- Nontender enlargement of regional lymph nodes.
- Fluid expressed from lesion contains T pallidum by immunofluorescence or darkfield microscopy.
- Serologic test for syphilis may be positive.

Clinical Findings

Symptoms and Signs

This is the stage of invasion and may pass unrecognized. The typical lesion is the chancre at the site or sites of inoculation, most frequently located on the penis, labia, cervix, or anorectal region (Plate 105). Anorectal lesions are especially common among men who have sex with men. Chancres also occur occasionally in the oropharynx (lip, tongue, or tonsil) and rarely on the breast or finger.

An initial small erosion 10–90 days (average, 3–4 weeks) after inoculation then rapidly develops into a painless superficial ulcer with a clean base and firm, indurated margins, which is associated with enlargement of regional lymph nodes, which are rubbery, discrete, and nontender. Bacterial infection of the chancre may occur and may lead to pain. Healing occurs without treatment, but a scar may form, especially with secondary bacterial infection. Multiple chancres may be present, particularly in HIV-positive patients. Although the "classic" ulcer of syphilis has been described as nontender, nonpurulent, and indurated, only 31% of patients have this triad.

Plate 105.

Primary syphilis with a large chancre on the glans of the penis. (Courtesy of Richard P. Usatine, MD; used, with permission, from Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H, Tysinger J. *The Color Atlas of Family Medicine*. McGraw-Hill, 2009.)

Laboratory Findings

Microscopic Examination

In early (infectious) syphilis, darkfield microscopic examination by a skilled observer of fresh exudate from lesions or material aspirated from regional lymph nodes is up to 90% sensitive for diagnosis. The darkfield examination requires considerable experience for proper specimen collection and identification of characteristic features of morphology and motility of pathogenic spirochetes, and repeated examinations may be necessary. Therefore, this testing is usually only available in select sexually transmitted disease clinics. Darkfield examination of oral lesions is not recommended because of the presence of nonpathogenic treponemes in the mouth. Spirochetes usually are not found in late syphilitic lesions by this technique.

An immunofluorescent staining technique for demonstrating *T pallidum* in dried smears of fluid taken from early syphilitic lesions is available. Slides are fixed and treated with fluorescein-labeled antitreponemal antibody that has been preabsorbed with nonpathogenic treponemes. The slides are then examined for fluorescing spirochetes in an ultraviolet microscope. Because of its simplicity and convenience to clinicians (slides can be mailed), this technique has replaced darkfield microscopy in most health departments and medical center laboratories.

Serologic Tests for Syphilis

(Table 34–2.) There are two general categories of serologic tests for syphilis: (1) Nontreponemal tests detect antibodies to lipoidal antigens present in the host after modification by *T pallidum*. (2) Treponemal tests use live or killed *T pallidum* as antigen to detect antibodies specific for pathogenic treponemes.

Table 34–2. Percentage of patients with positive serologic tests for syphilis.[1]

	Stage		
Test	**Primary**	**Secondary**	**Tertiary**
VDRL	70–75%	99%	75%
FTA-ABS	85–95%	100%	98%

[1] Based on untreated cases.

FTA-ABS, fluorescent treponemal antibody absorption test; VDRL, Venereal Disease Research Laboratory test.

Nontreponemal antigen tests

The most commonly used nontreponemal antigen tests are the Venereal Disease Research Laboratory (VDRL) and rapid plasma reagin (RPR), which measure the ability of heated serum to flocculate a suspension of cardiolipin–cholesterol–lecithin. The flocculation tests are inexpensive, rapid, and easy to perform and are therefore used primarily for routine screening. Quantitative expression of the reactivity of the serum, based on titration of dilutions of serum, is valuable in establishing the diagnosis and in evaluating the efficacy of treatment, since titers usually correlate with disease activity.

Nontreponemal tests generally become positive 4–6 weeks after infection, or 1–3 weeks after the appearance of a primary lesion; they are almost invariably positive in the secondary stage, with titers 1:32. In the late stages, titers tend to be lower (< 1:4). These serologic tests are not highly specific and must be closely correlated with other clinical and laboratory findings. The tests are positive in patients with non–sexually transmitted treponematoses (see below). More important, false-positive serologic reactions are frequently encountered in a wide variety of nontreponemal states, including connective tissue diseases, infectious mononucleosis, malaria, febrile diseases, leprosy, injection drug use, infective endocarditis, old age, hepatitis C viral infection, and pregnancy. False-positive tests also occur more commonly in HIV-seropositive patients (4%) than in HIV-seronegative patients (0.8%). False-positive reactions are usually of low titer and transient and may be distinguished from true positives by specific treponemal antibody tests. False-negative results can be seen when very high antibody titers are present (the prozone phenomenon). If syphilis is strongly suspected and the nontreponemal test is negative, the laboratory should be instructed to dilute the specimen to detect a positive reaction. The RPR and VDRL tests are equally reliable, but titers of RPR tend to be higher than the VDRL. Thus, when these tests are used to follow disease activity, the same testing method should be used and preferably should be performed at the same laboratory.

Nontreponemal antibody titers are used to assess adequacy of therapy. The time required for the VDRL or RPR to become negative depends on the stage of the disease, the level of the initial titer, and whether the infection is an initial or repeat episode. In general, persons with repeat infections, higher initial titers, more advanced stages of disease, or those who are HIV positive at the time of treatment have a slower seroconversion rate and are more likely to remain serofast (ie, titers do not become negative). Data based on currently recommended treatment regimens (see below) suggest that in primary and secondary syphilis it may take 6 months to see a fourfold decrease in titer and 12 months to see an eightfold drop. In patients with early latent syphilis, response is even slower, with a fourfold drop in titer taking 12–24 months. Seronegativity was seen in 72% of patients with primary syphilis and only 56% of those with secondary syphilis after 3 years.

Treponemal antibody tests

These tests measure antibodies capable of reacting with *T* *pallidum* antigens. The *T pallidum* hemagglutination (TPHA) test and the *T pallidum* particle agglutination (TPPA) test are comparable in specificity and sensitivity to the fluorescent treponemal antibody absorption test (FTA-ABS). The TPPA test, because of ease of performance, has supplanted the FTA-ABS test as the means of confirming the diagnosis of syphilis.

The treponemal tests are of value principally in determining whether a positive nontreponemal antigen test is false-positive or is indicative of syphilis. Because of their great sensitivity, particularly in the late stages of the disease, these tests are also of value when there is clinical evidence of syphilis but the nontreponemal serologic test for syphilis is negative. Treponemal tests are positive in most patients with primary syphilis and in almost all patients with secondary syphilis. Like nontreponemal antigen tests, the specific treponemal antibody test may revert to negative with adequate therapy. This is seen almost exclusively in initial infections in persons with primary syphilis. In one study, 11% of individuals with a first episode of primary syphilis were seronegative by the FTA-ABS test at 1 year posttreatment and 24% were negative by 3 years. Immunologic status may also affect antibody titers. Seven percent of asymptomatic HIV-infected patients became seronegative after treatment, compared with 38% of symptomatic HIV-infected individuals. The long-held belief that a positive treponemal test persists indefinitely is clearly not valid, and this test therefore cannot be used as a reliable marker of previous infection. False-positive test results occur rarely in persons with systemic lupus erythematosus and in other disorders associated with increased levels of -globulins, malaria, leprosy, and other spirochetal infections. It is noteworthy that Lyme disease may cause a false-positive treponemal test but rarely causes a false-positive nontreponemal test. Final decisions about the significance of the results of serologic tests for syphilis must be based on a total clinical appraisal.

Polymerase Chain Reaction

There is increasing interest in the use of polymerase chain reaction (PCR) for the diagnosis of genital ulcer disease, including syphilis, but it is not yet widely available in the United States.

Cerebrospinal Fluid Examination

See Neurosyphilis (below).

Differential Diagnosis

The syphilitic chancre may be confused with genital herpes, chancroid (usually painful and uncommon in the United States), lymphogranuloma venereum (also uncommon), or neoplasm. Any genital ulcer should be considered a possible primary syphilitic lesion. Simultaneous evaluation for herpes simplex virus types 1 and 2 using PCR or culture should also be done in these cases.

Prevention & Screening

Avoidance of sexual contact is the only completely reliable method of prevention but is an impractical public health measure for obvious reasons. The standard latex condom is effective but protects covered areas only. Screening every 6–12 months for syphilis among men who have sex with men has been recommended based on preliminary data suggesting that this may decrease the rate of transmission. High-risk individuals (those who have multiple encounters with anonymous partners or who have sex in conjunction with the use of drugs) should be screened every 3–6 months. Patients treated for other sexually transmitted diseases should also be tested for syphilis, and persons who have known or suspected contact with patients who have syphilis should be evaluated and treated to abort development of infectious syphilis (see Treating Syphilis Contacts below).

Treatment

Antibiotic Therapy

Penicillin remains the preferred treatment for syphilis, since there have been no documented cases of penicillin resistant *T pallidum* (Table 34–3). Although doxycycline is an alternative for some patients, pregnant women must be treated with penicillin (see below).

Table 34–3. Recommended treatment for syphilis.[1]

Stage of syphilis	**Treatment**	**Alternative[2]**	**Comment**
Early			
Primary, secondary, or early latent	Benzathine penicillin G 2.4 million units IM once	Doxycycline 100 mg orally twice daily for 14 days or tetracycline 500 mg orally four times daily for 28 days or ceftriaxone 1 g IM daily for 8–10 days	

Late			
Late latent or uncertain duration	Benzathine penicillin G 2.4 million units IM weekly for 3 weeks	Doxycycline 100 mg orally twice daily for 28 days or tetracycline 500 mg orally four times a day for 28 days	
Tertiary without neurosyphilis	Benzathine penicillin G 2.4 million units IM weekly for 3 weeks	Doxycycline 100 mg orally twice daily for 28 days or tetracycline 500 mg orally four times a day for 28 days	Cerebrospinal fluid evaluation recommended in all patients
Neurosyphilis	Aqueous	Procaine	Follow

	penicillin G 18-24 million units IV daily, given every 3-4 hours or as continuous infusion for 10-14 days	penicillin, 2.4 million units IM daily with probenicid 500 mg orally four times a day for 10–14 days or ceftriaxone 2 g IM daily for 10–14 days	treatment with benzathine penicillin G, 2.4 million units IM weekly for up to 3 weeks

[1] Penicillin is the only documented effective treatment in pregnancy, so pregnant patients with true allergy should be desensitized and treated with penicillin according to stage of disease as above.

[2] Patients treated with alternative therapies require close clinical and serologic monitoring.

There are limited data for ceftriaxone, although optimum dose and duration are not well defined. Azithromycin is no longer recommended due to increasing resistance.

Patients treated for neurosyphilis should receive at least one dose of long-acting penicillin at the completion of therapy. All patients treated with a non-penicillin regimen must have close clinical and serologic follow up, as noted below.

Local Measures (Mucocutaneous Lesions)

Local treatment is usually not necessary. No local antiseptics or other chemicals should be applied to a suspected syphilitic lesion until specimens for microscopy have been obtained.

Public Health Measures

Patients with infectious syphilis must abstain from sexual activity for 7–10 days after treatment, or until lesions have resolved. All cases of syphilis must be reported to the appropriate local public health agency for assistance in identifying and treating contacts. In addition, all patients with syphilis should have an HIV test at the time of diagnosis. In areas of high HIV prevalence, a repeat HIV test should be performed in 3 months if the initial test result was negative.

Treating Syphilis Contacts

Patients who have been sexually exposed to infectious syphilis within the preceding 3 months may be infected but seronegative and thus should be treated as for early syphilis. Persons exposed more than 90 days previously should be treated based on serologic results. If their partners are unavailable for testing or unreliable for follow-up, empiric therapy is indicated.

Persons at high risk for infection (ie, those with other sexually transmitted diseases and those infected with HIV) and pregnant women should undergo serologic tests for syphilis. Patients with gonorrhea and a known exposure to syphilis should be treated with separate regimens effective against both diseases.

Complications of Specific Therapy

The Jarisch–Herxheimer reaction, manifested by fever and aggravation of the existing clinical picture in the hours following treatment, is ascribed to the sudden massive destruction of spirochetes. It is most common in early syphilis, particularly secondary syphilis where it can occur in 66% of cases. The reaction resolves spontaneously within 24 hours; treatment should not be discontinued unless the symptoms become severe or life-threatening or unless syphilitic laryngitis, auditory neuritis, or labyrinthitis is present, where the reaction may cause irreversible damage. It may prompt preterm labor in pregnant women.

The reaction may be prevented or modified by simultaneous administration of antipyretics, although no proved method of prevention exists. Patients should be reminded it does not represent an allergic reaction to penicillin.

Follow-Up Care

Because treatment failures and reinfection may occur, patients treated for syphilis should be monitored clinically and serologically at 3–6 month intervals. Response to therapy may be difficult to assess, and no definite criteria exist for cure in patients with primary or secondary syphilis. In primary and secondary syphilis, failure of nontreponemal antibody titers to decrease fourfold by 6 months may identify a group at high risk for treatment failure. Optimal management of these patients is unclear, but at a minimum, close clinical and serologic follow-up is indicated. If titers fail to decrease fourfold by 6 months, an HIV test should be repeated (all patients with syphilis should have an HIV test at the time of diagnosis); a lumbar puncture should be considered since unrecognized neurosyphilis can be a cause of treatment failure; and, if careful follow-up cannot be ensured (3-month intervals for HIV-positive individuals and 6-month intervals for HIV-negative patients), treatment should be repeated with 2.4 million units of benzathine penicillin intramuscularly weekly for 3 weeks. If symptoms or signs persist or recur after initial therapy or there is a fourfold or greater increase in nontreponemal titers, therapy has either failed or the patient has been reinfected. In those individuals, an HIV test should be performed, a lumbar puncture done (unless reinfection is a certainty), and re-treatment given as indicated above.

Secondary Syphilis

Essentials of Diagnosis

- Generalized maculopapular skin rash.
- Mucous membrane lesions, including patches and ulcers.
- Weeping papules (condylomas) in moist skin areas.
- Generalized nontender lymphadenopathy.
- Fever.
- Meningitis, hepatitis, osteitis, arthritis, iritis.
- Many treponemes in scrapings of mucous membrane or skin lesions by immunofluorescence or darkfield microscopy.
- Serologic tests for syphilis always positive.

General Considerations & Treatment

The secondary stage of syphilis usually appears a few weeks (or up to 6 months) after development of the chancre, when dissemination of *T pallidum* produces systemic signs (fever, lymphadenopathy) or infectious lesions at sites distant from the site of inoculation. The most common manifestations are skin and mucosal lesions. The skin lesions are nonpruritic, macular, papular, pustular, or follicular (or combinations of any of these types, but *not* vesicular), though the maculopapular rash is the most common. The skin lesions usually are generalized; involvement of the palms and soles occurs in 80% of cases (Plate 106). Annular lesions simulating ringworm may be observed in dark-skinned individuals. Mucous membrane lesions range from ulcers and papules of the lips, mouth, throat, genitalia, and anus ("mucous patches") to a diffuse redness of the pharynx. Both skin and mucous membrane lesions are highly infectious at this stage. Specific lesions—**condylomata lata**—are fused, weeping papules on the moist areas of the skin and mucous membranes and are sometimes mistaken for genital warts.

Plate 106

Secondary syphilis lesions on the soles of the feet. (Courtesy of Dr. Gavin Hart, Public Health Image Library, CDC.)

Meningeal (aseptic meningitis or acute basilar meningitis), hepatic, renal, bone, and joint invasion may occur, with resulting cranial nerve palsies, jaundice, nephrotic syndrome, and periostitis. Alopecia (moth-eaten appearance) and uveitis may also occur.

The serologic tests for syphilis are positive in almost all cases (see Primary Syphilis, above). The moist cutaneous and mucous membrane lesions often show *T pallidum* on darkfield microscopic examination. A transient cerebrospinal fluid (CSF) pleocytosis is seen in 30–70% of patients with secondary syphilis, though only 5% have positive serologic CSF reactions. There may be evidence of hepatitis or nephritis (immune complex type). Circulating immune complexes exist in the blood and are deposited in blood vessel walls.

Skin lesions may be confused with the infectious exanthems, pityriasis rosea, and drug eruptions (Plate 107). Visceral lesions may suggest nephritis or hepatitis due to other causes. The diffusely red throat may mimic other forms of pharyngitis.

Plate 107

Secondary syphilis rash of the buttocks and legs. (Courtesy of J. Pledger, BSS/VD, Public Health Image Library, CDC.)

Treatment is as for primary syphilis unless central nervous system or ocular disease is present, in which case a lumbar puncture should be performed and, if positive, treatment is as for neurosyphilis (Table 34–3). Isolation of the patient is important. See Primary Syphilis for follow-up care and treatment of contacts.

Early Latent Syphilis

Essentials of Diagnosis

- No physical signs.
- History of syphilis with inadequate treatment.
- Positive serologic tests for syphilis.

General Considerations & Treatment

Latent syphilis is the clinically quiescent phase during the interval after the disappearance of secondary lesions and is defined as the first year after primary infection. Early latent syphilis may relapse to secondary syphilis if undiagnosed or inadequately treated (see above). Unlike the usual asymptomatic neurologic involvement of secondary syphilis, neurologic relapses may be fulminating, leading to death. Relapse is almost always accompanied by a rising titer in quantitative serologic tests; indeed, a rising titer may be the first or only evidence of relapse. About 90% of relapses occur during the first year after infection. If untreated, a small proportion of patients progress to tertiary syphilis.

Treatment and follow up is as for primary syphilis unless central nervous system disease is present (Table 34–3).

Late Latent ("Hidden") Syphilis

Essentials of Diagnosis

- No physical signs.
- History of syphilis with inadequate treatment.
- Positive serologic tests for syphilis.

General Considerations & Treatment

After the first year of latent syphilis, the patient is said to be in the late latent phase. Transmission to the fetus, however, can probably occur in any phase. There are (by definition) no clinical manifestations during the latent phase, and the only significant laboratory findings are positive serologic tests. A diagnosis of latent syphilis is justified only when the CSF is entirely negative, radiographic studies and physical examination show no evidence of cardiovascular involvement, and false-positive tests for syphilis have been ruled out. The latent phase may last from months to a lifetime.

Treatment of late latent syphilis is shown in Table 34–3. The treatment of this stage of the disease is intended to prevent the late sequelae. If there is evidence of central nervous system involvement, a lumbar puncture should be performed and, if positive, the patient should receive treatment as for neurosyphilis. Titers may not decline as rapidly following treatment as in early syphilis. Nontreponemal serologic tests should be repeated at 6, 12, and 24 months. If titers increase fourfold or if initially high titers (1:32) fail to decrease fourfold by 12–24 months or if symptoms or signs consistent with syphilis develop, an HIV test and lumbar puncture should be performed and re-treatment given according to the stage of the disease.

Late (Tertiary) Syphilis

Essentials of Diagnosis

- Infiltrative tumors of skin, bones, liver (gummas).
- Aortitis, aneurysms, aortic regurgitation.
- Central nervous system disorders, including meningovascular and degenerative changes, paresthesias, shooting pains, abnormal reflexes, dementia, or psychosis.

General Considerations

This stage may occur at any time after secondary syphilis, even after years of latency, and is rarely seen in the modern antibiotic era. Late lesions probably represent, at least in part, a delayed hypersensitivity reaction of the tissue to the organism and are usually divided into two types: (1) a localized gummatous reaction, with a relatively rapid onset and generally prompt response to therapy ("benign late syphilis") and (2) diffuse inflammation of a more insidious onset that characteristically involves the central nervous system and large arteries, is often fatal if untreated, and is at best arrested by treatment. Gummas may involve any area or organ of the body but most often affect the skin or long bones. Cardiovascular disease is usually manifested by aortic aneurysm, aortic regurgitation, or aortitis. Various forms of diffuse or localized central nervous system involvement may occur.

Late syphilis must be differentiated from neoplasms of the skin, liver, lung, stomach, or brain; other forms of meningitis; and primary neurologic lesions.

Although almost any tissue and organ may be involved in late syphilis, the following are the most common types of involvement: skin, mucous membranes, skeletal system, eyes, respiratory system, gastrointestinal system, cardiovascular system, and nervous system.

Clinical Findings

Symptoms and Signs

Skin

Cutaneous lesions of late syphilis are of two varieties: (1) multiple nodular lesions that eventually ulcerate (lues maligna) or resolve by forming atrophic, pigmented scars and (2) solitary gummas that start as painless subcutaneous nodules, then enlarge, attach to the overlying skin, and eventually ulcerate (Plate 108).

Plate 108

Gumma of the nose due to long-standing tertiary syphilis. (Courtesy of J. Pledger, Public Health Image Library, CDC.)

Mucous Membranes

Late lesions of the mucous membranes are nodular gummas or leukoplakia, highly destructive to the involved tissue.

Skeletal System

Bone lesions are destructive, causing periostitis, osteitis, and arthritis with little or no associated redness or swelling but often marked myalgia and myositis of the neighboring muscles (see x-ray). The pain is especially severe at night.

Fig.

Syphilis of the foot. A lesion of the fifth tarsometatarsal joint is shown, with destruction of bone on both sides of the joint and soft tissue swelling. There is also an increased periosteal reaction. Periosteal thickening involving the other metatarsals is seen, as well as destruction of the fifth metatarsophalangeal joint. (Courtesy of H Goldberg.)

Eyes

Late ocular lesions are gummatous iritis, chorioretinitis, optic atrophy, and cranial nerve palsies, in addition to the lesions of central nervous system syphilis.

Respiratory System

Respiratory involvement by late syphilis is caused by gummatous infiltrates into the larynx, trachea, and pulmonary parenchyma, producing discrete pulmonary densities. There may be hoarseness, respiratory distress, and wheezing secondary to the gummatous lesion itself or to subsequent stenosis occurring with healing.

Gastrointestinal System

Gummas involving the liver produce the usually benign, asymptomatic hepar lobatum. A picture resembling Laennec cirrhosis is occasionally produced by liver involvement. Gastric involvement can consist of diffuse infiltration into the stomach wall or focal lesions that endoscopically and microscopically can be confused with lymphoma or carcinoma. Epigastric pain, early satiety, regurgitation, belching, and weight loss are common symptoms.

Cardiovascular System

Cardiovascular lesions (10–15% of late syphilitic lesions) are often progressive, disabling, and life-threatening. Central nervous system lesions are often present concomitantly. Involvement usually starts as an arteritis in the supracardiac portion of the aorta and progresses to one or more of the following: (1) narrowing of the coronary ostia, with resulting decreased coronary circulation, angina, and acute myocardial infarction; (2) scarring of the aortic valves, producing aortic regurgitation, and eventually congestive heart failure; and (3) weakness of the wall of the aorta, with saccular aneurysm formation (Plate 109) and associated pressure symptoms of dysphagia, hoarseness, brassy cough, back pain (vertebral erosion), and occasionally rupture of the aneurysm. Recurrent respiratory infections are common as a result of pressure on the trachea and bronchi.

Plate 109

Ascending saccular aneurysm of the thoracic aorta in tertiary syphilis. (Public Health Image Library, CDC.)

Nervous System (Neurosyphilis)

See following section.

Treatment

Treatment of tertiary syphilis (excluding neurosyphilis) is the same as late latent syphilis (Table 34–3). Reversal of positive serologic tests does not usually occur. A second course of penicillin therapy may be given, but there is no known method for reliable eradication of the treponeme from humans in the late stages of syphilis. Viable spirochetes are occasionally found in the eyes, in CSF, and elsewhere in patients with "adequately" treated syphilis, but claims for their capacity to cause progressive disease are speculative.

In the presence of definite CSF or neurologic abnormalities, one should treat for neurosyphilis. The pretreatment clinical and laboratory evaluation should include neurologic, ocular, cardiovascular, psychiatric, and CSF examinations.

Neurosyphilis

Essentials of Diagnosis

- Can occur at any stage of disease.
- Consider both clinical presentation and laboratory data.
- Carefully evaluate HIV-positive patients and consider CSF evaluation for atypical symptoms or lack of decrease in nontreponemal serology titers.

General Considerations

Neurosyphilis can occur at any stage of disease and can be a progressive, disabling, and life-threatening complication. CSF pleocytosis has been reported in 10–20% of patients with primary syphilis. Asymptomatic and meningovascular syphilis occur earlier (months to years after infection, sometimes coexisting with primary and secondary syphilis) than tabes dorsalis and general paresis (2–50 years after infection).

Clinical Findings

Classification

There are four clinical types.

Asymptomatic Neurosyphilis

This form is characterized by spinal fluid abnormalities (positive spinal fluid serology, increased cell count, occasionally increased protein) without symptoms or signs of neurologic involvement.

Meningovascular Syphilis

This form is characterized by meningeal involvement or changes in the vascular structures of the brain (or both), producing symptoms of chronic meningitis (headache, irritability); cranial nerve palsies (basilar meningitis); unequal reflexes; irregular pupils with poor light and accommodation reflexes; and when large vessels are involved, cerebrovascular accidents. The CSF shows increased cells (100–1000/mcL), elevated protein, and usually a positive serologic test for syphilis. The symptoms of acute meningitis are rare in late syphilis.

Tabes Dorsalis

This form is a chronic progressive degeneration of the parenchyma of the posterior columns of the spinal cord and of the posterior sensory ganglia and nerve roots. The symptoms and signs are impairment of proprioception and vibration sense, Argyll Robertson pupils (which react poorly to light but well to accommodation), and muscular hypotonia and hyporeflexia. Impairment of proprioception results in a wide-based gait and inability to walk in the dark. Paresthesias, analgesia, or sharp recurrent pains in the muscles of the leg ("shooting" or "lightning" pains) may occur. Crises are also common in tabes: gastric crises, consisting of sharp abdominal pains with nausea and vomiting (simulating an acute abdomen); laryngeal crises, with paroxysmal cough and dyspnea; urethral crises, with painful bladder spasms; and rectal and anal crises. Crises may begin suddenly, last for hours to days, and cease abruptly. Neurogenic bladder with overflow incontinence is also seen. Painless trophic ulcers may develop over pressure points on the feet. Joint damage may occur as a result of lack of sensory innervation (Charcot joint, Plate 110). The CSF may have a normal or increased cell count (3–200/mcL), elevated protein, and variable results of serologic tests.

Plate 110

Neuropathic arthropathy (Charcot joint) from tertiary syphilis. (Courtesy of Susan Lindsley, Public Health Image Library, CDC.)

General Paresis

This is generalized involvement of the cerebral cortex with insidious onset of symptoms. There is usually a decrease in concentrating power, memory loss, dysarthria, tremor of the fingers and lips, irritability, and mild headaches. Most striking is the change of personality; the patient becomes slovenly, irresponsible, confused, and psychotic. The CSF findings resemble those of tabes dorsalis. Combinations of the various forms of neurosyphilis (especially tabes and paresis) are not uncommon.

Laboratory Findings

See Serologic Tests for Syphilis, above; these tests should also be performed in cases of suspected neurosyphilis.

Indications for a Lumbar Puncture

It is most important to prevent neurosyphilis by prompt diagnosis, adequate treatment, and follow-up of early syphilis. Indications for lumbar puncture vary depending on the stage of the disease and the patient's immune status. In early syphilis (primary and secondary syphilis and early latent syphilis of less than 1 year duration), invasion of the central nervous system by *T pallidum* with CSF abnormalities occurs commonly, but clinical neurosyphilis rarely develops in patients who have received the standard therapy outlined above. Thus, unless clinical symptoms and signs of neurosyphilis or ophthalmologic involvement (uveitis, neuroretinitis, optic neuritis, iritis) are present, a lumbar puncture in early syphilis is not recommended as part of the routine evaluation. In latent syphilis, the decision to perform a lumbar puncture should be individualized. Routine lumbar puncture for all patients is not indicated since the yield is low and findings rarely influence therapeutic decisions. CSF evaluation is recommended, however, in the later stages of syphilis if neurologic or ophthalmologic symptoms and signs are present, if therapy other than with penicillin is to be given, if the patient is HIV positive (see next section), if there is evidence of treatment failure (see earlier discussion), or if there is evidence of active tertiary syphilis (eg, aortitis, iritis, optic atrophy, the presence of a gumma). Some experts also routinely recommend lumbar puncture for all persons with latent syphilis if the serum nontreponemal antibody titer is 1:32 or the CD4 count is < 350/mcL in HIV-infected persons.

Spinal Fluid Examination

CSF findings in neurosyphilis are variable. In "classic" cases, there is an elevation of total protein, lymphocytic pleocytosis, and a positive CSF reagin test (VDRL). However, CSF may be completely normal in neurosyphilis, and the VDRL may be negative. In one study, 25% of patients with primary or secondary syphilis in whom *T pallidum* was isolated from CSF had normal findings. In later stages of syphilis, normal CSF analysis in the presence of infection can occur, but it is unusual. Because false-positive reagin tests rarely occur in the CSF, a positive test confirms the presence of neurosyphilis. Because the CSF VDRL may be negative in 30–70% of cases of neurosyphilis, *a negative test does not exclude neurosyphilis*. The CSF FTA-ABS is sometimes used; it is a highly sensitive test but lacks specificity, and a high serum titer of FTA-ABS may result in a positive CSF titer in the absence of neurosyphilis.

Treatment

Current recommendations for the therapy of neurosyphilis include higher doses of short-acting penicillin to achieve better penetration and higher levels of drug in the CSF than is possible with benzathine penicillin (Table 34–3). Because of concerns about slowly dividing organisms that may persist after only 10–14 days of therapy, many experts recommend subsequent administration of 2.4 million units of benzathine penicillin intramuscularly once weekly for up to 3 weeks as additional therapy. There are some data for using ceftriaxone as well, but because other regimens for neurosyphilis have not been adequately studied, patients with a history of an IgE-mediated reaction to penicillin should be skin tested for allergy to penicillin and, if positive, desensitized.

All patients should have nontreponemal serologic tests done every 3 months. Guidelines established by the Centers for Disease Control and Prevention (CDC) recommend spinal fluid examinations at 6-month intervals until the CSF cell count is normal; however, a recent study suggested that in certain patients normalization of serum titers are an acceptable surrogate for CSF response. In general, CSF white blood cell count and CSF VDRL normalize more quickly (usually in 12 months) than CSF protein concentration, which can remain abnormal for extended periods. If the serum nontreponemal titers do not normalize, the CSF analysis should be repeated. A second course of penicillin therapy may be given if the CSF cell count has not decreased at 6 months or is not normal at 2 years.

Syphilis in HIV-Infected Patients

Interpretation of serologic tests should be the same for HIV-positive and HIV-negative persons. Although unusual serologic responses have been reported in HIV-positive patients, including high titers of nontreponemal tests, delayed appearance of positive titers, and false-negative tests, most HIV-positive patients respond serologically in largely the same way as noninfected patients. All HIV-positive patients in care should be screened at least twice a year by RPR or VDRL to identify latent disease because by establishing a serologic history, unnecessary lumbar punctures and prolonged treatment for latent syphilis of uncertain duration can be avoided. If the diagnosis of syphilis is suggested on clinical grounds but reagin tests are negative, alternative tests should be performed. These tests include darkfield examination of lesions and direct fluorescent antibody staining for *T pallidum* of lesion exudate or biopsy specimens.

Treatment of HIV-positive patients with primary and secondary syphilis is the same as for HIV-negative patients. Because of concerns about the adequacy of this therapy, some experts recommend additional therapy with 2.4 million units of benzathine penicillin intramuscularly weekly for 3 weeks instead of single-dose therapy. However, despite occasional reports of neurosyphilis developing in HIV-infected patients despite appropriate therapy for early disease, most HIV-infected patients with primary or secondary syphilis respond appropriately to currently recommended regimens. In all cases, careful clinical and serologic follow-up should be done at 3, 6, 9, 12, and 24 months. HIV-infected patients with late latent syphilis, syphilis of uncertain duration, and neurosyphilis should be treated like HIV-negative individuals, with follow-up at 6, 12, 18, and 24 months. A study among HIV-clinic patients in Baltimore found that the use of antiretroviral therapy was associated with reduced serologic failure rates after syphilis treatment.

The diagnosis of neurosyphilis in HIV-infected patients is complicated by the fact that CSF abnormalities are frequently seen and may be due to neurosyphilis or HIV infection itself. The significance of these abnormalities is unknown, and similar abnormalities are frequently seen in non–HIV-infected patients with primary or secondary syphilis. Thus, although some experts recommend a CSF examination for all HIV-positive patients with syphilis, such testing is probably not needed in those with early disease. In contrast, a lumbar puncture should be performed in HIV-positive patients if they have late latent syphilis or syphilis of uncertain duration, if neurologic signs are present, or if therapy has failed. A recent study found that HIV-positive patients with a nontreponemal antibody titer 1:32 had a sixfold increased risk of having neurosyphilis, and if the CD4 count was 350/mcL, there was a threefold increased risk of neurosyphilis, suggesting that these subgroups should also undergo lumbar puncture. Following treatment, CSF white blood cell counts normalize within 12 months regardless of HIV status, while the CSF VDRL is slower to normalize in HIV-infected individuals, especially those with CD4 counts < 200 cells/mcL. As discussed above, the same criteria for failure apply to HIV-positive and HIV-negative patients, and re-treatment regimens are the same.

Because clinical experience in treating HIV-infected patients with syphilis is based on penicillin regimens, few options exist for treating the penicillin-allergic patient. Doxycycline or tetracycline regimens can be used for primary, secondary, and early latent syphilis as well as for late latent syphilis and latent syphilis of unknown duration though with caution and close follow-up. For neurosyphilis, penicillin regimens are optimal even if this requires skin testing and desensitization; limited data exist for ceftriaxone.

Syphilis in Pregnancy

All pregnant women should have a nontreponemal serologic test for syphilis at the time of the first prenatal visit. In women who may be at increased risk for syphilis or for populations in which there is a high prevalence of syphilis, additional nontreponemal tests should be performed during the third trimester at 28 weeks and again at delivery. The serologic status of all women who have delivered should be known before discharge from the hospital. Seropositive women should be considered infected and should be treated unless prior treatment with fall in antibody titer is medically documented.

The only acceptable treatment for syphilis in pregnancy is penicillin in dosage schedules appropriate for the stage of disease (see above). Penicillin prevents congenital syphilis in 90% of cases, even when treatment is given late in pregnancy. Tetracycline and doxycycline are contraindicated in pregnancy. Erythromycin should not be used because of failure to eradicate infection in the fetus, and insufficient data are available to justify a recommendation for ceftriaxone or azithromycin. Thus, women with a history of penicillin allergy should be skin tested and desensitized if necessary.

The infant should be evaluated immediately, as noted below, and at 6–8 weeks of age.

Congenital Syphilis

Congenital syphilis is a transplacentally transmitted infection that occurs in infants of untreated or inadequately treated mothers. The physical findings at birth are quite variable: The infant may have many or minimal signs or even no signs until 6–8 weeks of life (delayed form). The most common findings are on the mucous membranes and skin—maculopapular rash, condylomas, mucous membrane patches, and serous nasal discharge (snuffles). These lesions are infectious; *T pallidum* can easily be found microscopically, and the infant must be isolated. Other common findings are hepatosplenomegaly, anemia, or osteochondritis. These early active lesions subsequently heal, and if the disease is left untreated it produces the characteristic stigmas of syphilis—interstitial keratitis, Hutchinson teeth, saddle nose, saber shins, deafness, and central nervous system involvement.

The presence of negative serologic tests at birth in both the mother and the infant usually means that the newborn is free of infection. However, recent infection near the time of delivery may result in negative tests because there has been insufficient time to develop a serologic response. Thus, it is necessary to maintain a high index of suspicion in infants with delayed onset of symptoms despite negative serologic tests at birth, especially in infants born to high-risk mothers (HIV-positive, illicit drug users). All infants born to mothers with positive nontreponemal and treponemal antibody titers should have blood drawn for an RPR or VDRL test and, if positive, be referred to a pediatrician for further evaluation and therapy.

When to Refer

Consultation with the local public health department may help obtain all prior positive syphilis serologic results and may be helpful in complicated or atypical cases.

When to Admit

- Pregnant women with syphilis and true penicillin allergy should be admitted for desensitization and treatment.
- Women in late pregnancy treated for early syphilis should have close outpatient monitoring or be admitted because the Jarisch-Herxheimer reaction can induce premature labor.
- Patients with neurosyphilis usually require admission for treatment with aqueous penicillin.

Non-Sexually Transmitted Treponematoses: Introduction

A variety of treponemal diseases other than syphilis occur endemically in many tropical areas of the world. They are distinguished from disease caused by *T pallidum* by their nonsexual transmission, their relatively high incidence in certain geographic areas and among children, and their tendency to produce less severe visceral manifestations. As in syphilis, organisms can be demonstrated in infectious lesions with darkfield microscopy or immunofluorescence but cannot be cultured in artificial media; the serologic tests for syphilis are positive; the diseases have primary, secondary, and sometimes tertiary stages; and penicillin is the drug of choice. There is evidence that infection with these agents may provide partial resistance to syphilis and vice versa. Treatment with penicillin in doses appropriate to primary syphilis (eg, 2.4 million units of benzathine penicillin G intramuscularly) is generally curative in any stage of the non–sexually transmitted treponematoses. In cases of penicillin hypersensitivity, tetracycline, 500 mg orally four times a day for 10–14 days, is usually the recommended alternative.

Yaws (Frambesia)

Yaws is a contagious disease largely limited to tropical regions that is caused by *T pallidum* subspecies *pertenue*. It is characterized by granulomatous lesions of the skin, mucous membranes, and bone. Yaws is rarely fatal, though if untreated it may lead to chronic disability and disfigurement. Yaws is acquired by direct nonsexual contact, usually in childhood, although it may occur at any age. The "mother yaw," a painless papule that later ulcerates, appears 3–4 weeks after exposure. There is usually associated regional lymphadenopathy. Six to 12 weeks later, secondary lesions that are raised papillomas and papules that weep highly infectious material appear and last for several months or years. Painful ulcerated lesions on the soles are called "crab yaws" because of the resulting gait. Late gummatous lesions may occur, with associated tissue destruction involving large areas of skin and subcutaneous tissues. The late effects of yaws, with bone change, shortening of digits, and contractions, may be confused with similar changes occurring in leprosy. Central nervous system, cardiac, or other visceral involvement is rare. See above for therapy.

Pinta

Pinta is a non–sexually transmitted spirochetal infection caused by *Treponema carateum.* It occurs endemically in rural areas of Latin America, especially in Mexico, Colombia, and Cuba, and in some areas of the Pacific. A nonulcerative, erythematous primary papule spreads slowly into a papulosquamous plaque showing a variety of color changes (slate, lilac, black). Secondary lesions resemble the primary one and appear within a year after it. These appear successively, new lesions together with older ones; are most common on the extremities; and later show atrophy and depigmentation. Some cases show pigmentary changes and atrophic patches on the soles and palms, with or without hyperkeratosis, that are indistinguishable from "crab yaws." Very rarely, central nervous system or cardiovascular disease is observed late in the course of infection. See Non-Sexually Transmitted Treponematoses: Introduction for therapy.

Endemic Syphilis

Endemic syphilis is an acute or chronic infection caused by *T pallidum* subspecies *endemicum*. It has been reported in a number of countries, particularly in the eastern

Mediterranean area, often with local names: bejel in Syria, Saudi Arabia, and Iraq, and dichuchwa, njovera, and siti in Africa. It also occurs in Southeast Asia. The local forms have distinctive features. Moist ulcerated lesions of the skin or oral or nasopharyngeal mucosa are the most common manifestations. Generalized lymphadenopathy and secondary and tertiary bone and skin lesions are also common. Deep leg pain points to periostitis or osteomyelitis. In the late stages of disease, destructive gummatous lesions similar to those seen in yaws can develop, resulting in loss of cartilage and saber shin deformity. Cardiovascular and central nervous system involvement are rare. See above for therapy.

Relapsing Fever

Relapsing fever is endemic in many parts of the world. The main reservoir is rodents, which serve as the source of infection for ticks (eg, ornithodoros). The distribution and seasonal incidence of the disease are determined by the ecology of the ticks in different areas. In the United

States, infected ticks are found throughout the West, especially in mountainous areas, but clinical cases are uncommon in humans.

The infectious organisms are spirochetes of the genus *Borrelia.* The infection has two forms: tick-borne and louse-borne. Tick-borne relapsing fever may be transmitted transovarially from one generation of ticks to the next. Humans can be infected by tick bites or by rubbing crushed tick tissues or feces into the bite wound. Tick-borne relapsing fever is endemic but is not transmitted from person to person. Different species (or strain) names have been given to *Borrelia* in different parts of the world where the organisms are transmitted by different ticks.

The louse-borne form is primarily seen in the developing world. Large epidemics may occur in louse-infested populations, and transmission is favored by crowding, malnutrition, and cold climate.

Clinical Findings

Symptoms and Signs

There is an abrupt onset of fever, chills, tachycardia, nausea and vomiting, arthralgia, and severe headache. Hepatomegaly and splenomegaly may develop, as well as various types of rashes (macular, popular, petechial) that usually occur at the end of a febrile episode. Delirium occurs with high fever, and there may be various neurologic and psychic abnormalities. The attack terminates, usually abruptly, after 3–10 days. After an interval of 1–2 weeks, relapse occurs, but often it is somewhat milder. Three to ten relapses may occur before recovery in tick-borne disease, whereas louse-borne disease is associated with only one or two relapses.

Laboratory Findings

During episodes of fever, large spirochetes are seen in blood smears stained with Wright or Giemsa stain. The organisms can be cultured in special media but rapidly lose pathogenicity. The spirochetes can multiply in injected rats or mice and can be seen in their blood.

A variety of anti-borrelia antibodies develop during the illness; sometimes the Weil–Felix test for rickettsioses and nontreponemal serologic tests for syphilis may also be falsely positive. Infection with *B recurrentis* can cause false-positive indirect fluorescent antibody and Western blot tests for *Borrelia burgdorferi*, and some cases may be misdiagnosed as Lyme disease. CSF abnormalities occur in patients with meningeal involvement. Mild anemia and thrombocytopenia are common, but the white blood cell count tends to be normal.

Differential Diagnosis

The manifestations of relapsing fever may be confused with malaria, leptospirosis, meningococcemia, yellow fever, typhus, or rat-bite fever.

Prevention

Prevention of tick bites (as described for rickettsial diseases) and delousing procedures applicable to large groups can prevent illness. Arthropod vectors should be controlled if possible.

Doxycycline 200 mg orally on day 1 and 100 mg daily for 4 days has been shown to prevent recurrent fever following tick bites in highly endemic areas.

Treatment

A single dose of tetracycline or erythromycin, 0.5 g orally, or a single dose of procaine penicillin G, 400,000–600,000 units intramuscularly, probably constitutes adequate treatment for louse-borne relapsing fevers. Because of higher relapse rates, tick-borne disease is treated with 0.5 g of tetracycline or erythromycin given orally four times daily for 5–10 days. Jarisch–Herxheimer reactions occur commonly following treatment and may be life-threatening, so patients should be closely monitored. There is evidence that administration of anti-TNF antibodies prior to antibiotic therapy can be effective in preventing the reaction.

Prognosis

The overall mortality rate is usually about 5%. Fatalities are most common in old, debilitated, or very young patients. With treatment, the initial attack is shortened and relapses are largely prevented.

Rat-Bite Fever

Rat-bite fever is an uncommon acute infectious disease caused by the treponeme *Spirillum minus* (Asia), covered in this section, or the bacteria *Streptobacillus moniliformis* (North America). It is transmitted to humans by the bite of a rat. Inhabitants of rat-infested dwellings and laboratory workers are at greatest risk.

Clinical Findings

Symptoms and Signs

In *Spirillum* infections, the original rat bite, unless secondarily infected, heals promptly, but 1 to several weeks later the site becomes swollen, indurated, and painful; assumes a dusky purplish hue; and may ulcerate. Regional lymphangitis and lymphadenitis, fever, chills, malaise, myalgia, arthralgia, and headache are present. Splenomegaly may occur. A sparse, dusky-red maculopapular rash appears on the trunk and extremities in many cases, and there may be frank arthritis.

After a few days, both the local and systemic symptoms subside, only to reappear several days later. This relapsing pattern of fever for 3–4 days alternating with afebrile periods lasting 3–9 days may persist for weeks. The other features, however, usually recur only during the first few relapses. Endocarditis is a rare complication of infection.

Laboratory Findings

Leukocytosis is often present, and the nontreponemal test for syphilis is often falsely positive. The organism may be identified in darkfield examination of the ulcer exudate or aspirated lymph node material; more commonly, it is observed after inoculation of a laboratory animal with the patient's exudate or blood. It has not been cultured in artificial media.

Differential Diagnosis

Rat-bite fever must be distinguished from the rat-bite–induced lymphadenitis and rash of streptobacillary fever. Clinically, the severe arthritis and myalgias seen in streptobacillary disease are rarely seen in disease caused by *S minus*. Reliable differentiation requires an increasing titer of agglutinins against *S moniliformis* or isolation of the causative organism. Other diseases in the differential include tularemia, rickettsial disease, *Pasteurella multocida* infections, and relapsing fever.

Treatment

Penicillin is given for 10–14 days. During the acute phase of illness, the intravenous route is used (1–2 million units every 4–6 hours) and once improvement has occurred, therapy is completed with oral medication, penicillin V 500 mg four times daily to complete 10–14 days of therapy. For the penicillin-allergic patient, tetracycline 500 mg orally four times daily or doxycycline 100 mg twice a day can be used.

Prognosis

The reported mortality rate of about 10% should be markedly reduced by prompt diagnosis and antimicrobial treatment.

Elliot SP. Rat bite fever and *Streptobacillus moniliformis*. Clin Microbiol Rev. 2007 Jan;20(1):13–22. [PMID: 17223620]

Leptospirosis

Essentials of Diagnosis

- Clinical illness can vary from asymptomatic to fatal liver and kidney disease.
- Anicteric leptospirosis is the more common and milder form of the disease.
- Icteric leptospirosis (Weil syndrome) is characterized by impaired kidney and liver function, abnormal mental status, and hemorrhagic pneumonia and has a 5–40% mortality rate.

General Considerations

Leptospirosis is an acute and often severe treponemal infection that frequently affects the liver or other organs and is caused by multiple species within the genus *Leptospira*. The disease is worldwide in distribution, and it is among the most common zoonotic diseases. The leptospires are often transmitted to humans by the ingestion of food and drink contaminated by the urine of the reservoir animal. The organism may also enter through minor skin lesions and probably via the conjunctiva. Recreational cases have followed swimming or rafting in contaminated water, and occupational cases occur among sewer workers, rice planters, abattoir workers, and farmers. Sporadic urban cases have been seen in the homeless exposed to rat urine. The incubation period is 2–20 days.

Clinical Findings

Symptoms and Signs

Anicteric leptospirosis, the more common and milder form of the disease, is often biphasic. The initial or "septicemic" phase begins with abrupt fever to 39–40 °C, chills, abdominal pain, severe headache, and myalgias, especially of the calf muscles. There may be marked conjunctival suffusion. Leptospires can be isolated from blood, CSF, and tissues. Following a 1- to 3-day period of improvement in symptoms and absence of fever, the second or "immune" phase begins. Leptospires are absent from blood and CSF but are still present in the kidney, and specific antibodies appear. A recurrence of symptoms is seen as in the first phase of disease with the onset of meningitis. Uveitis (which can be unilateral or bilateral and usually involves the entire uveal tract), rash, and adenopathy may occur. A rare but severe manifestation is hemorrhagic pneumonia. The illness is usually self-limited, lasting 4–30 days, and complete recovery is the rule.

Icteric leptospirosis (Weil syndrome) is the most severe form of the disease, characterized by impaired kidney and liver function, abnormal mental status, hemorrhagic pneumonia, hypotension, and a 5–40% mortality rate. Symptoms and signs often are continuous and not biphasic.

Pretibial fever, a mild form of leptospirosis caused by

Leptospira autumnalis, occurred during World War II at Fort Bragg. In pretibial fever, there is patchy erythema on the skin of the lower legs or generalized rash occurring with fever.

Leptospirosis with jaundice must be distinguished from hepatitis, yellow fever, and relapsing fever.

Laboratory Findings

The leukocyte count may be normal or as high as 50,000/mcL, with neutrophils predominating. The urine may contain bile, protein, casts, and red cells. Oliguria is common, and in severe cases uremia may occur. Elevated bilirubin and aminotransferases are seen in 75%, and elevated creatinine (> 1.5 mg/dL) is seen in 50% of cases. In cases with meningeal involvement, organisms may be found in the CSF during the first 10 days of illness. Early in the disease, the organism may be identified by darkfield examination of the patient's blood (a test requiring expertise since false-positives are frequent in inexperienced hands) or by culture on a semisolid medium (eg, Fletcher EMJH). Cultures take 1–6 weeks to become positive. The organism may also be grown from the urine from the tenth day to the sixth week. Diagnosis is usually made by means of serologic tests, of which several are available. Agglutination tests (microscopic, using live organisms, and macroscopic, using killed antigen) become positive after 7–10 days of illness, peak at 3–4 weeks, and may persist at high levels for many years. Thus, to make a diagnosis, a fourfold or greater rise in titer must be documented. The agglutination tests are cumbersome to perform and require trained personnel. Indirect hemagglutination and enzyme-linked immunosorbent assay (ELISA) tests are also available. The IgM EIA is particularly useful in making an early diagnosis, since it is positive as early as 2 days into illness, a time when the clinical manifestations may be nonspecific, and it is extremely sensitive and specific (93%). PCR methods (presently investigational) appear to be sensitive, specific, positive early in disease, and able to detect leptospiral DNA in blood, urine, CSF, and aqueous humor. Serum creatine kinase (CK) is usually elevated in persons with leptospirosis and normal in persons with hepatitis.

Complications

Myocarditis, aseptic meningitis, acute kidney injury, and pulmonary infiltrates with hemorrhage are not common but are the usual causes of death. Iridocyclitis may occur.

Prevention

The mainstay of prevention is avoidance of potentially contaminated food and water.

Prophylaxis with doxycycline, 200 mg orally once weekly, can be given during periods of possible exposure.

Human vaccine is used in some limited settings but is not widely available.

Treatment

Various antimicrobial drugs, including penicillin, ceftriaxone, and tetracyclines, show antileptospiral activity. Penicillin (eg, 1.5 million units every 6 hours intravenously) or ceftriaxone (1 g daily intravenously) is the drug of choice in severe leptospirosis and is especially effective if started within the first 4 days of illness. Jarisch–Herxheimer reactions may occur. Doxycycline, 100 mg orally twice daily for 7 days, is also effective as therapy if started early, but this agent is most often used in mild to moderate disease. Although therapy for mild disease is controversial, most clinicians treat with oral penicillin, 500 mg four times daily, or doxycycline, 100 mg orally twice daily, for 7 days. Azithromycin is also active, but clinical experience is limited.

Prognosis

Without jaundice, the disease is almost never fatal. With jaundice, the mortality rate is 5% for those under age 30 years and 30% for those over age 60 years.

Lyme Disease (Lyme Borreliosis)

Essentials of Diagnosis

- Erythema migrans, a flat or slightly raised red lesion that expands with central clearing.
- Headache or stiff neck.
- Arthralgias, arthritis, and myalgias; arthritis is often chronic and recurrent.
- Wide geographic distribution, with most United States cases in the Northeast, mid-Atlantic, upper Midwest, and Pacific coastal regions.

General Considerations

This illness, named after the town of Old Lyme, Connecticut, is the most common tickborne disease in the United States and Europe. In the United States, the causative organism is the spirochete *B burgdorferi*, whereas in Europe and Asia the predominant organisms are *Borrelia garinii* and *Borrelia afzelii*. Most cases (90%) are reported from the mid-Atlantic, northeastern, and north central regions of the country, whereas far fewer cases are reported from the West Coast. The true incidence of Lyme disease is not known and overreporting continues to be a problem for a number of reasons: (1) serologic tests are not standardized (see below); (2) clinical manifestations are nonspecific; (3) even with reliable testing, serology is insensitive in early disease; and (4) other as yet unidentified organisms may cause illnesses similar to Lyme disease, eg, the Lone Star tick (*Amblyomma americanum*) found in the midwestern and southern regions of the United States can carry a spirochete that produces skin lesions indistinguishable from erythema migrans.

The vector of Lyme disease varies geographically and is *Ixodes scapularis* in the northeastern, north central, and mid-Atlantic regions of the United States; *Ixodes pacificus* on the West Coast; *Ixodes ricinus* in Europe; and *Ixodes persulcatus* in Asia. The disease also occurs in Australia. Mice and deer make up the major animal reservoir of *B burgdorferi*, but other rodents and birds may also be infected. Domestic animals such as dogs, cattle, and horses can also develop clinical illness, usually manifested as arthritis.

Ticks feed once during each of their three stages of life.

Larval ticks feed in late summer, nymphs in the following spring and early summer, and adults during the fall. In the northeastern United States and the mid-Atlantic states, the preferred host for the nymphs and larvae is the white-footed mouse (the black-striped mouse in Europe). This animal is tolerant of infection—a fact that is critical in maintaining infection, since the mouse can remain spirochetemic and transmit the agent to the larvae the following spring after being infected by the nymphal form in early summer. Adult ticks prefer the white-tailed deer as host. Although only 20–25% of nymphs harbor spirochetes compared with 50–65% of adults, most infections occur in the spring and summer (when nymphs are active), and fewer cases occur in the cooler months (October to April), when adults feed. This is probably due to the greater abundance of nymphs; greater human outdoor activity in spring and summer, when nymphs feed; and the fact that adult ticks are larger, easier to detect by the human host, and thus can be removed before disease is transmitted. Less than 1% of larvae are infected with spirochetes, and transmission of the disease through contact with larvae is unlikely. In the western United States, the *I pacificus* nymph prefers to feed on lizards, which are not susceptible to infection. It is only the few nymph and larval ticks that feed on wood rats, which can be infected, that are capable of transmitting disease.

Under experimental conditions, ticks must feed for 24–36 hours or longer to transmit infections. Human epidemiologic studies have indicated that the incidence of disease is significantly higher when tick attachment is for longer than 72 hours than if it is less than 72 hours, though rare cases have been documented with attachment of less than 24 hours. In addition, the percentage of ticks infected varies on a regional basis. In the northeastern and midwestern regions, 15–65% of *I scapularis* ticks are infected with the spirochete; in the western United States, only 2% of *I pacificus* are infected. These are important epidemiologic features in assessing the likelihood that tick exposure will result in disease. Exposure to *I pacificus* is unlikely to result in disease, since so few ticks are infected, but this is not true of exposure to *I scapularis*. Eliciting a history of brushing a tick off the skin (ie, the tick was not feeding) or removing a tick on the same day as exposure (ie, the tick did not feed long enough) decreases the likelihood that infection will develop.

Ixodes ticks are smaller than the more common dog ticks *(Dermacentor variabilis)*. Larvae are less than 1 mm in size, and the adult female is 2–3 mm in size, with a red body and black legs. After a blood meal, ticks can reach two to three times their unengorged size. Because the tick is so small, the bite is usually painless and goes unnoticed. After feeding, the tick drops off in 2–4 days. If a tick is found, it should be removed immediately. The best way to accomplish this is to use a fine-tipped tweezers to pull firmly and repeatedly on the tick's mouth part—not the tick's body—until the tick releases its hold. Saving the tick in a bottle of alcohol for future identification may be useful, especially if symptoms develop.

Congenital infection has been documented, but the exact frequency and manifestations have not been clearly defined. Similarly, because the organism can be latent, it is not known if women infected prior to becoming pregnant can activate the disease and transmit infection to the fetus. In one retrospective study, 5 of 19 pregnancies complicated by Lyme disease resulted in an adverse outcome, but all of the outcomes were different and could not be conclusively linked to infection. Several serosurveys involving over 2000 pregnant women in endemic areas have not found any association between seropositivity in prospective mothers and the prevalence of congenital malformations, fetal death, and prematurity. Thus, if *B burgdorferi* causes a congenital syndrome like some other spirochetal illnesses, it must be extremely uncommon.

Clinical Findings

The typical clinical description of Lyme disease divides the illness into three stages: stage 1, flu-like symptoms and a typical skin rash (**erythema migrans,** Plate 32);

stage 2, weeks to months later, Bell palsy or meningitis; and stage 3, months to years later, arthritis. The problem with this simplified scheme is that there is a great deal of overlap, and the skin, central nervous system, and musculoskeletal system can be involved early or late. A more accurate classification divides disease into early and late manifestations and specifies whether disease is localized or disseminated.

Plate 32

Erythema migrans due to *Borrelia burgdorferi* (Lyme disease). (Courtesy of James Gathany, Public Health Image Library, CDC).

Symptoms and Signs

Stage 1, Early Localized Infection

Stage 1 infection is characterized by erythema migrans. About 1 week after the tick bite (range, 3–30 days; median 7–10 days), a flat or slightly raised red lesion appears at the site, which is commonly seen in areas of tight clothing such as the groin, thigh, or axilla. This lesion expands over several days. Although originally described as a lesion that progresses with central clearing ("bulls-eye" lesion), often there is a more homogeneous appearance or even central intensification. About 10–20% of patients either do not have typical skin lesions or the lesions go unnoticed. Most patients with erythema migrans will have a concomitant viral-like illness (the "summer flu") characterized by myalgias, arthralgias, headache, and fatigue. Fever may or may not be present. Even without treatment, the symptoms and signs of erythema migrans resolve in 3–4 weeks. Although the classic lesion of erythema migrans is not difficult to recognize, atypical forms can occur that may lead to misdiagnosis. Vesicular, urticarial, and evanescent erythema migrans have all been reported. Similarly, chemical reactions to tick and spider bites (these usually recede in 24–48 hours whereas erythema migrans increases in size in this time period), drug eruptions, urticaria, and staphylococcal and streptococcal cellulitis have been mistaken for erythema migrans.

Completely asymptomatic disease, without erythema migrans or flu-like symptoms, can occur but is very uncommon in the United States. Serosurveys done as part of vaccination trials found asymptomatic seroconversion in 7% or less of the population.

Stage 2, Early Disseminated Infection

Up to 50–60% of patients with erythema migrans are bacteremic (especially if multiple lesions are present) leading to dissemination of the spirochete resulting in a wide variety of symptoms and signs. Within days to weeks of the original infection, secondary skin lesions that are not associated with a tick bite develop in about 50% of patients. These lesions are similar in appearance to the primary lesion but are usually smaller. Malaise, fatigue, fever, headache (sometimes severe), neck pain, and generalized achiness are common with the skin lesions. Most symptoms are transient, although fatigue may persist for months. After hematogenous spread, the organism may sequester itself in certain areas and produces focal symptoms. Some patients experience cardiac (4–10% of patients) or neurologic (10–15% of patients) manifestations. Involvement of the heart includes myopericarditis, with atrial or ventricular arrhythmias and heart block. Neurologic manifestations include both the central and peripheral nervous systems. The most common central nervous system manifestation is an aseptic meningitis with mild headache and neck stiffness. The most common peripheral manifestation is a cranial neuropathy, ie, Bell palsy (usually unilateral but can be bilateral, Plate 90). A sensory or motor radiculopathy and mononeuritis multiplex occur less frequently. Conjunctivitis, keratitis and, rarely, panophthalmitis can also occur.

Plate 90

Facial palsy caused by an infection with *Borrelia burgdorferi* (Lyme disease). (Public Health Image Library, CDC.)

Stage 3, Late Persistent Infection

Stage 3 infection occurs months to years after the initial infection and again primarily manifests itself as musculoskeletal, neurologic, and skin disease. In early reports, musculoskeletal complaints developed in up to 60% of patients. With early recognition and treatment of disease, joint complaints develop in less than 10% of patients. The classic manifestation of late disease is a monarticular or oligoarticular arthritis most commonly affecting the knee or other large weight bearing joints. Knees are swollen out of proportion to the pain experienced by the patient. Even if untreated, the arthritis is self-limited, resolving in a few weeks to months. Multiple recurrences are common but are usually less severe than the original disease. Joint fluid reflects an inflammatory arthritis with a mean white blood cell count of 25,000/mcL with a predominance of neutrophils. Chronic arthritis develops in about 10% of patients. The pathogenesis of chronic Lyme arthritis may be an immunologic phenomenon rather than persistence of infection. The observations that persons with chronic arthritis have an increased frequency of HLA-DR4 gene expression, antibodies to OspA and OspB protein in joint fluid (major outer surface proteins of *B burgdorferi*), lack *B burgdorferi* DNA in synovial fluid as detected by PCR, and often do not respond to antibiotics—all support the inference of an immunologic mechanism.

Rarely, the nervous system (both central and peripheral) can be involved in late Lyme disease. In the United States, a subacute encephalopathy, characterized by memory loss, mood changes, and sleep disturbance, is seen. In Europe, a more severe encephalomyelitis caused by *B garinii* is seen and presents with cognitive dysfunction, spastic paraparesis, ataxia, and bladder dysfunction. Peripheral nervous system involvement includes intermittent paresthesias, often in a stocking glove distribution, or radicular pain.

The cutaneous manifestation of late infection, which can occur up to 10 years after infection, is **acrodermatitis chronicum atrophicans.** It has been described mainly in Europe and is due to infection with *B afzelii*, a species that commonly causes disease in Europe but not the United States. There is usually bluish-red discoloration of a distal extremity with associated swelling. These lesions become atrophic and sclerotic with time and eventually resemble localized scleroderma. At least two cases of diffuse fasciitis with eosinophilia, a rare entity that resembles scleroderma, have been associated with infection with *B burgdorferi*.

Laboratory Findings

The diagnosis of Lyme disease is based on both clinical manifestations and laboratory findings. The National Surveillance Case Definition specifies a person with exposure to a potential tick habitat (within the 30 days just prior to developing erythema migrans) with (1) erythema migrans diagnosed by a physician or (2) at least one late manifestation of the disease and (3) laboratory confirmation as fulfilling the criteria for Lyme disease.

Laboratory confirmation requires detection of specific antibodies to *B burgdorferi* in serum, either by indirect immunofluorescence assay (IFA) or ELISA; the latter is preferred because it is more sensitive and specific. A Western blot assay that can detect both IgM and IgG antibodies is used as a confirmatory test. IgM antibody appears first 2–4 weeks after onset of erythema migrans, peaks at 6–8 weeks, and then declines to low levels after 4–6 months of illness. The presence of IgM antibody in patients with prolonged symptoms persisting for several months is likely to be a false-positive result. IgG occurs later (6–8 weeks after onset of disease), peaks at 4–6 months, and may remain elevated at low levels indefinitely despite appropriate therapy and resolution of symptoms. A two-test approach is recommended for the diagnosis of active Lyme disease. All specimens positive or equivocal by ELISA or IFA should be tested by Western immunoblot. When Western immunoblot is done during the first 4 weeks of illness, both IgM and IgG should be tested. If a patient with suspected early Lyme disease has negative serologic studies, acute and convalescent titers should be obtained since up to 50% of patients with early disease can be antibody negative in the first several weeks of illness. A fourfold rise in antibody titer would be diagnostic of recent infection. In patients with later stages of disease, almost all are antibody positive. False-positive reactions in the ELISA and IFA have been reported in juvenile rheumatoid arthritis, rheumatoid arthritis, systemic lupus erythematosus, infectious mononucleosis, subacute infective endocarditis, syphilis, relapsing fever, leptospirosis, enteroviral and other viral illnesses, and patients with gingival disease (presumably because of cross-reactivity with oral treponemes). False-negative serologic reactions occur early in illness, and antibiotic therapy early in disease can abort subsequent seroconversion.

An ELISA test measures antibodies against a peptide in the invariant region of VlsE, an outer surface lipoprotein of *B burgdorferi*. The test is done in a single step (as opposed to the current two-step test recommended by the Centers for Disease Control and Prevention), is easy to standardize, and is less expensive than two-step testing. The ELISA appears to be as sensitive and specific as the current two-step test in the diagnosis of late stage disease and it is more sensitive for early disease.

Caution should be exercised in interpreting serologic tests because they are not subject to national standards, and inter-laboratory variation is a major problem. In addition, some laboratories perform tests that are entirely unreliable and should never be used to support the diagnosis of Lyme disease (eg, the Lyme urinary antigen test, immunofluorescent staining for cell wall-deficient forms of *B burgdorferi*, lymphocyte transformation tests, using PCR on inappropriate specimens such as blood or urine). Finally, testing is often done in patients with nonspecific symptoms such as headache, arthralgia, myalgia, fatigue, and palpitations. Even in endemic areas, the pretest probability of having Lyme disease is low in these patients, and the probability of a false-positive test result is greater than that of a true-positive result. For these reasons, the American College of Physicians has established guidelines for laboratory evaluation of patients with suspected Lyme disease:

1. The diagnosis of early Lyme disease is clinical (ie, exposure in an endemic area, with physician-documented erythema migrans), and does *not* require laboratory confirmation. (Tests are often negative at this stage.)
2. Late disease requires objective evidence of clinical

manifestations (recurrent brief attacks of monarticular or oligoarticular arthritis of the large joints; lymphocytic meningitis, cranial neuritis [Bell palsy], peripheral neuropathy or, rarely, encephalomyelitis—but *not* headache, fatigue, paresthesias, or stiff neck alone; atrioventricular conduction defects with or without myocarditis) and laboratory evidence of disease (two-stage testing with ELISA and Western blot, as described above).

3. Patients with nonspecific symptoms without objective signs of Lyme disease should *not* have serologic testing done. It is in this setting that false-positive tests occur more commonly than true-positive tests.
4. The role of serologic testing in neuroborreliosis is unclear, as sensitivity and specificity of CSF serologic tests have not been determined. However, it is rare for a patient with neuroborreliosis to have positive serologic tests on CSF without positive tests on serum (see below).
5. Other tests such as the T cell proliferative assay, PCR testing, and urinary antigen detection have not yet been studied well enough to be routinely used (see discussion below).

Cultures for *B burgdorferi* can be performed but are not routine and are usually reserved for clinical studies. Aspiration of erythema migrans lesions has yielded positive cultures in up to 30% of cases, whereas culture of a 2-mm punch biopsy is positive in 50–70%. PCR of a skin biopsy is even more sensitive, with positivity rates of 80%. In early disease, blood cultures are positive in up to 50% if large volumes (9 mL) are used, but CSF is rarely culture positive. The ability to culture organisms from skin lesions is greatly influenced by antibiotic therapy. Even a brief course of several days will result in negative cultures. Special silver staining of chronically inflamed synovial tissue demonstrates spirochetes in one-third of patients..

PCR is very specific for detecting the presence of *Borrelia* DNA, but sensitivity is variable and depends on which body fluid is tested and the stage of the disease. In general, PCR is more sensitive than culture, especially in chronic disease. Up to 85% of synovial fluid samples are positive in active arthritis. In contrast, 38% of CSF samples in acute neuroborreliosis are PCR positive, and only 25% are positive in chronic neuroborreliosis. The significance of a positive reaction is unclear. Whether a positive PCR indicates persistence of viable organisms that will respond to further treatment or is a marker for residual DNA (not active infection) has not been clarified. In chronic Lyme arthritis, some have suggested that a positive PCR indicates active infection that requires further therapy, while others have found a positive reaction despite months of therapy, suggesting that the presence of DNA is indicative of an autoimmune arthritis.

The diagnosis of late **neuroborreliosis** is often difficult since clinical manifestations, such as subtle memory impairment, may be difficult to document. Most patients with neuroborreliosis have a history of previous erythema migrans or monarticular or polyarticular arthritis, and the vast majority have antibody present in serum. When CSF is sampled from patients with encephalopathy, there may be evidence of inflammation (pleocytosis or elevated protein, or both), and localized antibody production, ie, a ratio of CSF to serum antibody of > 1.0. The role of other tests such as PCR in detection of DNA or ELISA in detecting the presence of outer surface protein A (OspA) antigen is unclear, but in difficult cases these tests can be performed and, if positive, help establish the diagnosis. Patients with late disease and peripheral neuropathy almost always have positive serum antibody tests, usually have abnormal electrophysiology tests, and may have abnormal nerve biopsies showing perivascular collections of lymphocytes. Because disease involves peripheral nerves, the cerebral spinal fluid is usually normal and does not demonstrate local antibody production.

Nonspecific laboratory abnormalities can be seen, particularly in early disease. The most common are an elevated sedimentation rate of > 20 mm/h seen in 50% of cases and mildly abnormal liver function tests present in

30%. The abnormal liver function tests are transient and return to normal within a few weeks of treatment. A mild anemia, leukocytosis (11,000–18,000/mcL), and microscopic hematuria have been reported in 10% or less of patients.

Prevention

Simple preventive measures such as avoiding tick-infested areas, covering exposed skin with long-sleeved shirts and wearing long trousers tucked into socks, wearing light-colored clothing, using repellents, and inspecting for ticks after exposure will greatly reduce the number of tick bites. Environmental controls directed at limiting ticks on residential property would be helpful, but trying to limit the deer, tick, or white-footed mouse populations over large areas is not feasible.

Prophylactic antibiotics following tick bites is recommended in certain high risk situations if all of the following criteria are met: (1) a tick identified as an adult or nymphal *I scapularis* has been attached for at least 36 hours; (2) prophylaxis can be started within 72 hours of the time the tick was removed; (3) more than 20% of ticks in the area are known to be infected with *B burgdorferi;* and (4) there is no contraindication to the use of doxycycline (not pregnant, age greater than 8 years, not allergic). As noted above, *I scapularis* ticks in the northeastern, mid-Atlantic, and upper midwestern states are infected with *B burgdorferi* at a high rate (> 20%) whereas *I pacificus* ticks on the West Coast are not (about 2%). The drug of choice for prophylaxis is a single 200 mg dose of doxycycline. If doxycycline is contraindicated, no prophylaxis should be given, since short course prophylactic therapy with other agents has not been studied and if early disease does develop appropriate therapy is very effective in preventing long-term sequelae. Individuals who have removed ticks (including those who have had prophylaxis) should be monitored carefully for 30 days. If skin lesions or a viral-like illness develop, they should be evaluated for possible Lyme disease, human granulocytic anaplasmosis, and babesiosis. There is no human vaccine currently available.

Treatment

Antibiotic sensitivity of B burgdorferi has been established in vitro. Tetracycline is effective against the spirochete, but penicillin is only moderately so. Erythromycin is effective in vitro but has been disappointing in clinical trials. Ampicillin, ceftriaxone, azithromycin, cefuroximine, and imipenem are also effective in vitro, but aminoglycosides, ciprofloxacin, and rifampin are not.

Present recommendations for therapy are outlined in Table 34–4. For erythema migrans, antibiotic therapy shortens the duration of rash and prevents late sequelae.

Doxycycline, is most commonly used and has the advantage of being active against *Anaplasma phagocytophilum* (formerly *Ehrlichia*). Amoxicillin is also effective and is recommended for pregnant or lactating women and for those who cannot tolerate doxycycline. Cefuroxime axetil, is as effective as doxycycline, but because of its cost it should be considered an alternative choice for those who cannot tolerate doxycycline or amoxicillin or for those in whom the drugs are contraindicated. Erythromycin and azithromycin are less effective, associated with higher rates of relapse, and are not recommended as first-line therapy.

Table 34–4. Treatment of Lyme disease.

Manifestation	**Drug and Dosage**
Tick bite	No treatment in most circumstances (see text); observe
Erythema migrans	Doxycycline, 100 mg orally twice daily, or amoxicillin, 500 mg orally three times daily, or cefuroxime axetil, 500 mg orally twice daily—all for 2–3 weeks
Neurologic disease	
Bell palsy (without	Doxycycline, amoxicillin, or

meningitis)	cefuroxime axetil as above for 2–3 weeks
Other central nervous system disease	Ceftriaxone, 2 g intravenously once daily, or penicillin G, 18–24 million units daily intravenously in six divided doses, or cefotaxime, 2 g intravenously every 8 hours—all for 2–4 weeks
Cardiac disease	
Atrioventricular block and myopericarditis[1]	An oral or parenteral regimen as described above can be used
	Ceftriaxone or penicillin G as above for 2–3 weeks
Arthritis	
Oral dosage	Doxycycline, amoxicillin, or cefuroxime axetil as above for 28 days (see text)
Parenteral dosage	Ceftriaxone, cefotaxime, or penicillin G as above for 2–4 weeks
Acrodermatitis chronicum atrophicans	Doxycycline, amoxicillin, or cefuroxime axetil as above for 3 weeks

"Chronic Lyme disease" or "post-Lyme disease syndrome"	Symptomatic therapy

[1] Symptomatic patients, those with second- or third-degree block and those with first-degree block with a PR interval 30 milliseconds should be hospitalized for observation.

Isolated Bell palsy (without meningitis or peripheral neuropathy) can be treated with doxycycline, amoxicillin, or cefuroxime axetil for 2–3 weeks. Although therapy does not affect the rate of resolution of the cranial neuropathy, it does prevent development of late manifestations of disease.

The need for a lumbar puncture in patients with seventh nerve palsy is controversial. Some clinicians perform lumbar puncture on all patients with Bell palsy and others only if there are symptoms or signs of meningitis. If meningitis is present, therapy with a parenteral antibiotic is indicated. Ceftriaxone, is most commonly used, but penicillin is equally efficacious. In European countries, doxycycline 400 mg/d for 14 days is frequently used and is comparable in efficacy to ceftriaxone.

Patients with atrioventricular block or myopericarditis (or both) can be treated with either oral or parenteral agents for 2–3 weeks. Hospitalization and observation is indicated for symptomatic patients, those with second- or third-degree block, and those with first-degree block with a PR interval 30 milliseconds. Once stabilized, hospitalized patients can be transitioned to one of the oral regimens to complete therapy.

Therapy of arthritis is difficult because some patients do not respond to any therapy, and those who do respond may do so slowly. Oral agents (doxycycline, amoxicillin, or cefuroxime axetil) are as effective as intravenous regimens (ceftriaxone, cefotaxime, or penicillin). A reasonable approach to the patient with Lyme arthritis is to start with oral therapy for 28 days, and if this fails (persistent or recurrent joint swelling), to re-treat with an oral regimen for 28 days or switch to an intravenous regimen for 2–4 weeks. If some improvement has occurred with initial treatment with an oral regimen, another course of oral therapy is reasonable. If there has been no response or worsening with initial oral therapy, a parenteral regimen should be used. Re-treatment should be delayed for several months because of the slow resolution of joint symptoms. If arthritis persists after re-treatment, symptomatic therapy with nonsteroidal anti-inflammatory drugs is recommended. For severe refractory pain, synovectomy may be required.

Based on the limited published data, therapy of Lyme disease in pregnancy should be the same as therapy in other patients with the exception that doxycycline should not be used.

Clinicians are often confronted with patients with nonspecific symptoms (such as fatigue and myalgias) and positive serologic tests for Lyme disease who request (or demand) therapy for their illness. It is important in managing these patients to remember (1) that the diagnosis of Lyme disease is primarily a clinical one, and nonspecific symptoms alone are not diagnostic; (2) that serologic tests are fraught with difficulty (as noted above), and in areas where disease prevalence is low, false-positive serologic tests are much more common than true-positive tests; and (3) that parenteral therapy with ceftriaxone for 2–4 weeks is costly (approximately $5000) and has been associated with significant adverse effects (cholelithiasis). Parenteral therapy should be reserved for those most likely to benefit, ie, those with cutaneous, neurologic, cardiac, or rheumatic manifestations that are characteristic of Lyme disease.

Coinfections

Lyme disease, babesiosis (see Chapter 35: Protozoal & Helminthic Infections), and human granulocytic anaplasmosis (formerly human granulocytic ehrlichiosis) (see Chapter 32: Viral & Rickettsial Infections) are endemic in similar areas of the country and are transmitted by the same tick, *I scapularis*. Coinfection with two or even all three of these organisms can occur, causing a clinical picture that is not "classic" for any of these diseases. The presence of erythema migrans is highly suggestive of Lyme disease, whereas flu-like symptoms without rash are more suggestive of babesiosis or anaplasmosis. The complete blood count is usually normal in Lyme disease, but in patients with Lyme disease and babesiosis, anemia and thrombocytopenia are more common. Patients with Lyme disease and anaplasmosis are more likely to have leukopenia. Coinfection should be considered and excluded in patients who have persistent high fevers 48 hours after starting appropriate therapy for Lyme disease; in patients with persistent symptoms despite resolution of rash; and in those with anemia, leukopenia, or thrombocytopenia.

Even in patients with documented Lyme disease, immunity is not complete. Reinfection, although uncommon, is predominantly seen in patients successfully treated for early disease (erythema migrans) who do not develop antibody titers. Clinical manifestations and serologic response is similar to an initial infection.

Prognosis

Most patients respond to appropriate therapy with prompt resolution of symptoms within 4 weeks. True treatment failures are thus uncommon, and in most cases re-treatment or prolonged treatment of Lyme disease is instituted because of misdiagnosis or misinterpretation of serologic results (both IgG and IgM antibodies can persist for prolonged periods despite adequate therapy) rather than inadequate therapy or response. The terms "chronic Lyme disease" or "post-Lyme disease syndrome" have been applied to a heterogeneous group of patients with documented Lyme disease who have been adequately treated but have persistent poorly defined, nonspecific symptoms such as fatigue, arthralgias, myalgias, and neurocognitive complaints. Although some providers treat these patients with multiple or prolonged courses of oral or intravenous antibiotics, there are no data suggesting that this is efficacious, and the prolonged use of antibiotics in this setting is emphatically discouraged.

The long-term outcome of adult patients with Lyme disease is generally favorable, but some patients have chronic complaints. Joint pain, memory impairment, and poor functional status secondary to pain are common subjective complaints in patients with Lyme disease, but physical examination and neurocognitive testing fail to document the presence of these symptoms as objective sequelae. Similarly, in highly endemic areas, patients with a diagnosis of Lyme disease commonly complain of pain, fatigue, and an inability to perform certain physical activities when followed for several years. However, these complaints occur just as commonly in age-matched controls without a history of Lyme disease. Attempts to document chronic cardiac disease in patients treated for Lyme disease also have been unsuccessful. The long-term outcome of treated neuroborelliosis is favorable, with complete recovery in 75% of patients. Of the remaining individuals, only 12% had sequelae that affected their daily activities.

When to Refer

Consultation with an infectious diseases specialist with experience in treating Lyme disease can be helpful in atypical or prolonged cases.

When to Admit

Admission for parenteral antibiotics is indicated for any patient with symptomatic CNS or cardiac disease as well as those with second- or third-degree atrioventricular block, or first-degree block with a PR interval 30 milliseconds.

African Trypanosomiasis (Sleeping Sickness)

Essentials of Diagnosis

- Exposure to tsetse flies, with subsequent bite lesion.
- Irregular fever, headache, joint pain, rash, edema, lymphadenopathy progressing to somnolence, and neurologic abnormalities.
- Trypanosomes in blood or lymph node aspirates; positive serologic tests.
- Trypanosomes and increased white cells and protein

in cerebrospinal fluid.

General Considerations

African trypanosomiasis is caused by the hemoflagellates *Trypanosoma brucei rhodesiense* and *Trypanosoma brucei gambiense*. The organisms are transmitted by bites of tsetse flies (genus *Glossina*), which inhabit shaded areas along streams and rivers. Trypanosomes ingested in a blood meal develop over 18–35 days in the fly; when the fly feeds again on a mammalian host, the infective stage is injected. Human disease occurs in rural areas of sub-Saharan Africa from south of the Sahara to about 15 degrees south latitude. *T b gambiense* causes West African trypanosomiasis, and is transmitted in the moist sub-Saharan savannas and forests of west and central Africa. *T b rhodesiense* causes East African trypanosomiasis, and is transmitted in the savannas of east and southeast Africa.

T b rhodesiense infection is primarily a zoonosis of game animals and cattle; humans are infected sporadically. Humans are the principal mammalian host for *T b gambiense*, but domestic animals can be infected (see illustration). African trypanosomiasis is an increasing threat, especially where control has been disrupted by civil strife. The largest number of cases is in the Democratic Republic of the Congo. Annual incidence estimates are about 100,000 cases and 48,000 deaths, mostly due to *T b gambiense*, leading to the loss of 1.5 million disability-adjusted life years. Infections are rare among travelers, including visitors to game parks.

Fig.

Life cycle of *Trypanosoma brucei gambiense*. The agent of chronic (West African) sleeping sickness has no clearly identified alternative or reservoir final hosts other than humans–thus, the disease appears to be chiefly an anthroponosis. The human final host provides infective blood to the tsetse vector, chiefly *Glossina palpalis* and other riverine species. The trypomastigotes in human blood (1), ingested by the tsetse, change from trypomastigotes (chiefly as "stumpy forms") (2) to epimastigotes, which move to the salivary glands, multiply (3), and change to infective metacyclic trypomastigotes (4), the infective stage to the human host. Clinical Findings

Symptoms and Signs

West African Trypanosomiasis

Chancres at the site of the bite are uncommon. After an asymptomatic period that may last for months, hemolymphatic disease presents with fever, headache, myalgias, arthralgias, weight loss, and lymphadenopathy, with discrete, nontender, rubbery nodes, referred to as Winterbottom's sign when in a posterior cervical distribution. Other common signs are mild splenomegaly, transient edema, and a pruritic erythematous rash. Febrile episodes may be broken by afebrile periods of up to several weeks. The hemolymphatic stage progresses over months to meningoencephalitic disease, with somnolence, irritability, personality changes, severe headache, and parkinsonian symptoms progressing to coma and death.

East African Trypanosomiasis

Chancres are more commonly recognized with *T b rhodesiense* infection, with a painful lesion of 3–10 cm and regional lymphadenopathy that appears about 48 hours after the tsetse fly bite and lasts 2–4 weeks. East African disease follows a much more acute course, with the onset of symptoms usually within a few days of the insect bite. The hemolymphatic stage includes intermittent fever and rash, but lymphadenopathy is less common than with West African disease. Myocarditis can cause tachycardia and death due to arrhythmias or heart failure. If untreated, East African trypanosomiasis progresses over weeks to months to meningoencephalitic disease, somnolence, coma, and death.

Laboratory Findings

Definitive diagnosis requires identification of trypanosomes. Microscopic examination of fluid expressed from a chancre or lymph node may show motile trypanosomes or, in fixed specimens, parasites stained with Giemsa. During the hemolymphatic stage, detection of parasites in Giemsa-stained blood smears is common in East African disease but difficult in West African disease. Serial specimens should be examined, since parasitemias vary greatly over time. With meningoencephalitic disease, cerebrospinal fluid (CSF) shows increased mononuclear cells and protein as well as trypanosomes. Concentration techniques can aid identification of parasites in blood or CSF. Serologic tests are also available. The simple card agglutination test for trypanosomes (CATT) has excellent sensitivity and specificity and can be performed in the field; however, the diagnosis should be confirmed by identification of the parasites (see illustration).

Treatment

Detection of trypanosomes is a prerequisite for treatment of African trypanosomiasis because of the significant toxicity of most available therapies. Treatment recommendations depend on the type of trypanosomiasis, which is determined by geography, and stage of disease, which requires examination of CSF (Table 35–1).

Table 35–1. Treatment of African trypanosomiasis.

Disease	**Stage**	**Treatment**	
		First Line	**Alternative**
West	Early	Pentamidine	Suramin

African			Eflornithine
	CNS involvement	Eflornithine	Melarsoprol Eflornithine Nifurtimox
East African	Early	Suramin	Pentamidine
	CNS involvement	Melarsoprol	

CNS, central nervous system.

West African Trypanosomiasis

Early Stage Infection

Pentamidine (4 mg/kg intramuscularly or intravenously every day or every other day for 7 days) is used to treat infection that does not involve the central nervous system (CNS). The side effects of pentamidine include immediate hypotension; tachycardia; gastrointestinal symptoms during administration; sterile abscesses; and pancreatic, liver, and kidney abnormalities. An alternate drug is eflornithine (100 mg/kg/d intravenously every 6 hours for 14 days).

Late Stage Infection

Eflornithine is the drug of choice for infection that involves the CNS; the dosage is the same as that used to treat early disease. Eflornithine has less toxicity than older trypanocidal drugs, but it can cause gastrointestinal symptoms and bone marrow suppression and is limited by lack of availability and the need for frequent infusions. Alternative therapies are melarsoprol (see below) or nifurtimox (5 mg/kg orally three times per day for 14 days), and drug combinations may offer improved efficacy over monotherapies, with simplified regimens and decreased doses of toxic drugs.

East African Trypanosomiasis

Pentamidine and eflornithine are not reliably effective, and early disease is treated with suramin. The dosing regimens of suramin vary (eg, 100–200 mg test dose, then 20 mg/kg [maximum 1 g] intravenously on days 1, 3, 7, 14, and 21 or weekly for 5 doses). Suramin toxicities include vomiting and, rarely, seizures and shock during infusions as well as subsequent fever, rash, headache, neuropathy, and kidney and bone marrow dysfunction.

Suramin does not enter the CNS, so East African trypanosomiasis involving the CNS is treated with melarsoprol (three series of 3.6 mg/kg/d intravenously for 3 days, with 7-day breaks between the series or a 10-day intravenous course with 0.6 mg/kg on day 1, 1.2 mg/kg on day 2, and 1.8 mg/kg on days 3–10). Although melarsoprol acts against both early West and East African disease, it is very toxic. Immediate side effects of melarsoprol include fever and gastrointestinal symptoms. The most important side effect is a reactive encephalopathy that can progress to seizures, coma, and death. To help avoid this side effect, corticosteroids are coadministered (recommended regimens include dexamethasone 1 mg/kg/d intravenously for 2-3 days or oral prednisolone 1 mg/kg/d for 5 days, and then 0.5 mg/kg/d until treatment completion). In addition, increasing resistance to melarsoprol is a serious concern. Suramin and melarsoprol are available in the United States from the CDC Drug Service, Centers for Disease Control and Prevention, Atlanta, GA 30333; telephone: 404-639-3670.

Prevention & Control

Individual prevention in endemic areas should include long sleeves and pants, insect repellents, and mosquito nets. Control programs focusing on vector elimination and treatment of infected persons and animals have shown good success in many areas but suffer from limited resources.

American Trypanosomiasis (Chagas Disease)

Essentials of Diagnosis

Acute Stage

- Inflammatory lesion at inoculation site.
- Fever.
- Hepatosplenomegaly.
- Lymphadenopathy.
- Myocarditis.
- Parasites in blood is diagnostic.

Chronic Stage

- Heart failure, cardiac arrhythmias.
- Thromboembolism.
- Megaesophagus.
- Megacolon.
- Serologic tests are usually diagnostic.

General Considerations

Chagas disease is caused by *Trypanosoma cruzi*, a protozoan parasite found only in the Americas; it infects wild animals and to a lesser extent humans from southern South America to the southern United States. An estimated 10–12 million people are infected, mostly in rural areas, resulting in about 45,000 deaths annually. The disease is often acquired in childhood. In many countries in South America, Chagas disease is the most important cause of heart disease. In the United States, the vector is found and some animals are infected, but only a few instances of local transmission have been reported.

T cruzi is transmitted by reduviid (triatomine) bugs infected by ingesting blood from animals or humans who have circulating trypanosomes (see photograph). Multiplication occurs in the digestive tract of the bug and infective forms are eliminated in feces. Infection in humans occurs when the parasite penetrates the skin through the bite wound, mucous membranes, or the conjunctiva. Transmission can also occur by blood transfusion or in utero (see illustration). From the bloodstream, *T cruzi* invades many cell types but has a predilection for myocardium, smooth muscle, and CNS glial cells. Multiplication causes cellular destruction, inflammation, and fibrosis, with progressive disease over decades.

Fig.

Life cycle of *Trypanosoma cruzi* . A triatomine cone-nosed bug deposits infected feces while it feeds on a child. A woman holds an armadillo (commonly infected) dug out from under the house. Rubbing infective bug feces into the eye causes an acute sensitization reaction (Romaña's sign) or an enlarged heart or colon. At bottom, the vector bug is shown feeding. ***1–7:*** Trypomastigotes are found in the peripheral blood during the early, acute phase (1). Tissue cells are subsequently invaded, and there the parasites change to amastigotes and divide asexually (2). A common site for damaging infection is within heart muscle cells (3), causing enlargement and thinning of the organ and sometimes resulting in a terminal aneurysm. Parasympathetic ganglia attacked in the bowel can result in megacolon. Bugs feeding on infected peripheral blood pick up trypomastigotes (4), which briefly become promastigotes (5) and multiply as epimastigotes (6), then concentrate in the bug's liquid feces as infective metacyclic trypomastigotes (7). Clinical Findings

Symptoms and Signs

As many as 70% of infected persons remain asymptomatic. The **acute stage** is seen principally in children and lasts 1–2 months. The earliest findings are at the site of inoculation either in the eye—Romaña sign (unilateral edema, conjunctivitis, and lymphadenopathy)—or in the skin—a chagoma (swelling with local lymphadenopathy) (see photograph). Subsequent findings include fever, malaise, headache, mild hepatosplenomegaly, and generalized lymphadenopathy. Acute myocarditis and meningoencephalitis are rare but can be fatal.

Fig.

Romãna's sign. (Reproduced, with permission, from Goldsmith R, Heyneman D [editors]: *Tropical Medicine and Parasitology*. Originally published by Appleton &

Lange. Copyright © 1989 by The McGraw-Hill Companies, Inc.)

An asymptomatic latent period (indeterminate phase) may last for life, but symptomatic disease develops in 10–30% of infected individuals, commonly many years after infection.

Chronic Chagas disease generally manifests as abnormalities in cardiac and smooth muscle (see photograph). Cardiac disease includes arrhythmias, congestive heart failure, and embolic disease. Smooth muscle abnormalities lead to megaesophagus and megacolon, with dysphagia, regurgitation, aspiration, constipation, and abdominal pain. These findings can be complicated by superinfections. In immunosuppressed persons, including AIDS patients and transplant recipients, latent Chagas disease may reactivate; findings have included brain abscesses.

Parasitology. Originally published by Appleton & Lange. Copyright © 1989 by The McGraw-Hill Companies, Inc.)

Diagnostic Testing

Diagnosis should be considered in persons with suggestive findings who have resided in an endemic area. Transmission by blood transfusion and congenital transmission should also be considered. The diagnosis is made by detecting parasites. With **acute** infection, evaluation of fresh blood or buffy coats may show motile trypanosomes (see micrograph), and fixed preparations may show Giemsa-stained parasites. Trypanosomes may be identified in lymph nodes, bone marrow, or pericardial or spinal fluid. When initial tests are unrevealing in a suspicious case, xenodiagnosis, using laboratory vectors, laboratory culture, or animal inoculation may provide a diagnosis, but these methods are expensive and slow.

Fig.

A typical trypomastigote of *Trypanosoma cruzi* from an acute case of Chagas' disease. (Reproduced, with permission, from Goldsmith R, Heyneman D [editors]: *Tropical Medicine and Parasitology*. Originally

Chronic Chagas disease is usually diagnosed serologically. Many different serologic assays are available, but sensitivity and specificity are not ideal, so confirmatory assays are advised after an initial positive test, as is standard for blood bank testing in South America. Polymerase chain reaction (PCR) may offer an important new modality for diagnosis, but sensitivity of PCR assays has been disappointing.

Treatment

Treatment is inadequate because the two drugs used, nifurtimox and benznidazole, often cause severe side effects, must be used for long periods, and are ineffective against chronic infection. In acute and congenital infections, the drugs can reduce the duration and severity of infection, but cure is achieved in only about 70% of patients. During the chronic phase of infection, although parasitemia may disappear in up to 70% of patients, treatment does not clearly alter the progression of the disease. Nevertheless, there is general consensus that treatment should be considered in all *T cruzi*-infected persons regardless of clinical status or time since infection.

Nifurtimox is given orally in daily doses of 8–10 mg/kg in four divided doses after meals for 90–120 days. Side effects include gastrointestinal and neurologic symptoms, which appear to be reversible and to lessen with dosage reduction. Benznidazole is an alternative therapy that is given orally at a dosage of 5 mg/kg/d in divided doses for 60 days. Its side effects include granulocytopenia, rash, and peripheral neuropathy. In the United States, nifurtimox and benznidazole are available only from the CDC Drug Service, Centers for Disease Control and Prevention, Atlanta, GA 30333; telephone: 404-639-3670. Patients with chronic Chagas disease may also benefit from antiarrhythmic therapy, standard therapy for congestive heart failure, and conservative and surgical management of megaesophagus (see x-ray) and megacolon.

Prevention & Control

In South America, a major eradication program based on improved housing, use of residual pyrethroid insecticides and pyrethroid-impregnated bed curtains, and screening of blood donors has achieved striking reductions in new infections. In endemic areas and ideally in donors from endemic areas, blood should not be used for transfusion unless at least two serologic tests are negative.

Leishmaniasis

Essentials of Diagnosis

- Sand fly bite in an endemic area.
- Visceral leishmaniasis: irregular fever, progressive hepatosplenomegaly, pancytopenia, wasting.
- Cutaneous leishmaniasis: chronic, painless, moist ulcers or dry nodules.
- Mucocutaneous leishmaniasis: destructive nasopharyngeal lesions.
- Amastigotes in macrophages in aspirates, touch preparations, or biopsies.
- Positive culture, serologic tests, PCR, or skin test.

General Considerations

Leishmaniasis is a zoonosis transmitted by bites of sand flies of the genus *Lutzomyia* in the Americas and *Phlebotomus* elsewhere. When sand flies feed on an infected host, the parasitized cells are ingested with the blood meal. Leishmaniasis is caused by about 20 species of *Leishmania;* taxonomy is complex. Clinical syndromes are generally dictated by the infecting species, but some species can cause more than one syndrome.

An estimated 350 million persons are at risk for leishmaniasis. The estimated annual incidence of disease is 1–1.5 million new cases of cutaneous and 500,000 cases of visceral disease, leading to an estimated 50,000–60,000 deaths. The incidence of disease is increasing in many areas.

Visceral leishmaniasis (kala azar) is caused mainly by *Leishmania donovani* in the Indian subcontinent and East Africa; *Leishmania infantum* in the Mediterranean, Middle East, China, parts of Asia, and Horn of Africa; and *Leishmania chagasi* in South and Central America. Other species may occasionally cause visceral disease. Over 90% of cases occur in five countries: India, Bangladesh, Nepal, Sudan, and Brazil. In each locale, the disease has particular clinical and epidemiologic features. The incubation period is usually 4–6 months (range: 10 days to 24 months). Without treatment, the fatality rate reaches 90%. Early diagnosis and treatment reduces mortality to 2–5%.

Old World cutaneous leishmaniasis is caused mainly by *Leishmania tropica*, *Leishmania major*, and *Leishmania aethiopica* in the Mediterranean, Middle East, Africa, Central Asia, and Indian subcontinent. New World cutaneous leishmaniasis is caused by *Leishmania mexicana* and *Leishmania amazonensis* in Central and

South America (see illustration). Mucocutaneous leishmaniasis (espundia) occurs in lowland forest areas of the Americas and is caused by *Leishmania braziliensis*, *Leishmania panamensis*, and *Leishmania peruviana* (see photograph).

Fig.

Epidemiology of New World cutaneous leishmaniasis. ***A:*** Cutaneous leishmaniasis (chiclero's ulcer). Woodcutters collecting chicle in Yucatan are frequently bitten by *Lutzomyia* sand flies infected with *Leishmania mexicana mexicana* from arboreal rodents. A common clinical result is infection of the ear, with breakdown of the cartilage of the pinna. ***B:*** Cutaneous leishmaniasis (uta). A self-healing immunogenic cutaneous lesion is typical of infection with *Leishmania braziliensis peruviana* , a species found in the high (dry) western slopes of the Andes. The dog is the most important reservoir. The large granulomatous lesion will result in a typical pitted scar with a rolled or ridged border. ***C:*** Mucocutaneous leishmaniasis (espundia). A woodcutter in the Amazonian rain forest acquires infection from a

Lutzomyia sand fly that has fed on an infected arboreal mammal such as the two-toed sloth (inset). Espundia develops in perhaps one-third of cases of infection with *Leishmania braziliensis braziliensis*, resulting in breakdown of nasal cartilage and mucosal linings and sometimes a gross enlargement of the lip or nose, termed tapir trunk (right). Clinical Findings

Symptoms and Signs

Visceral Leishmaniasis (Kala azar)

Most infections are subclinical, but a small number progress to full-blown disease. A local nonulcerating nodule at the site of the sand fly bite may precede systemic manifestations but usually is inapparent. The onset of illness may be acute, within 2 weeks of infection, or insidious. Symptoms and signs include fever, chills, sweats, weakness, anorexia, weight loss, cough, and diarrhea. The spleen progressively becomes greatly enlarged, firm, and nontender. The liver is somewhat enlarged, and generalized lymphadenopathy may occur. Hyperpigmentation of skin can be seen, leading to the name kala azar ("black fever"). Other signs include skin lesions, petechiae, gingival bleeding, jaundice, edema, and ascites. As the disease progresses, severe wasting and malnutrition are seen; death eventually occurs often due to secondary infections, within months to a few years. Post-kala azar dermal leishmaniasis may appear after apparent cure in the Indian subcontinent and Sudan. It may simulate leprosy, with hypopigmented macules or nodules developing on preexisting lesions. Viscerotropic leishmaniasis has been reported in small numbers of American military personnel in the Middle East, with mild systemic febrile illnesses after *L tropica* infections.

Cutaneous Leishmaniasis

Cutaneous swellings appear 2 weeks to several months after sand fly bites and can be single or multiple.

Characteristics of lesions and courses of disease vary depending on the leishmanial species and host immune response. Lesions begin as small papules and develop into nonulcerated dry plaques or large encrusted ulcers with well-demarcated raised and indurated margins (Plate 111); (see photograph); (see photograph). Satellite lesions may be present. The lesions are painless unless secondarily infected. Local lymph nodes may be enlarged. Systemic symptoms are uncommon, but fever, constitutional symptoms, and regional lymphadenopathy may be seen. For most species, healing occurs spontaneously in months to a few years, but scarring is commonly seen (see photograph).

Fig.

Two cases of chronic nonhealing leishmaniasis recidivans. ***A:*** Satellite lesions developing around an old sore. ***B:*** Severe facial scarring following granulomatous tissue formation. (Courtesy of G Rahim, S Ahmed, and ADM Bryceson.)

Leishmaniasis recidivans is a relapsing form of *L tropica* infection associated with hypersensitivity, in which the primary lesion heals centrally, but spreads laterally, with extensive scarring. Diffuse cutaneous leishmaniasis involves spread from a central lesion to local dissemination of nodules and a protracted course. Disseminated cutaneous leishmaniasis involves multiple nodular or ulcerated lesions, often with mucosal involvement.

Mucocutaneous Leishmaniasis (Espundia)

In Latin America, mucosal lesions develop in a small percentage of persons infected with *L braziliensis* and some other species, usually months to years after resolution of a cutaneous lesion. Nasal congestion is followed by ulceration of the nasal mucosa and septum, progressing to involvement of the mouth, lips, palate, pharynx, and larynx. Extensive destruction can occur, and secondary bacterial infection is common. Similar syndromes have been reported with some other species in other areas.

Infections in Patients with AIDS

Leishmaniasis is an opportunistic infection in persons with AIDS seen in southern Europe and other areas. Visceral leishmaniasis can present late in the course of HIV infection, with fever, hepatosplenomegaly, and pancytopenia. The gastrointestinal tract, respiratory tract, and skin may also be involved.

Laboratory Findings

Identifying parasites in tissue samples or culture material provides a definitive diagnosis. In **visceral leishmaniasis,** fine-needle aspiration of the spleen for culture and tissue evaluation is generally safe, and yields a diagnosis in over

95% of cases. Bone marrow aspiration is less sensitive but safer and diagnostic in most cases. Giemsa-stained buffy coat of peripheral blood may occasionally show organisms. For all tissue biopsies and touch preparations, Giemsa staining will show amastigotes within macrophages. Cultures with media available from the CDC will grow promastigotes within a few days to weeks. PCR can also identify the infection. Inoculation of laboratory animals can also be used but is time consuming. Species are identified by molecular, isoenzyme, and monoclonal antibody methods. Serologic tests may facilitate diagnosis, but none are sufficiently sensitive or specific to be used alone. Antibody levels are typically high with visceral leishmaniasis but not cutaneous disease. For **cutaneous lesions,** biopsies should be taken from the raised border of a skin lesion, with samples for histopathology, touch preparation, and culture. The histopathology shows inflammation with mononuclear cells. Macrophages filled with amastigotes may be present, especially early in infection. An intradermal leishmanin (Montenegro) skin test is positive in most individuals with cutaneous disease but negative in those with progressive visceral or diffuse cutaneous disease; this test is not approved in the United States. In **mucocutaneous leishmaniasis,** diagnosis is established by detecting amastigotes in scrapings, biopsy preparations, or aspirated tissue fluid, but organisms may be rare. Cultures from these samples may grow organisms. Serologic studies are often negative, but the leishmanin skin test is usually positive.

Treatment

Treatment is not adequate because most drugs are quite toxic, require long courses, and are mostly administered parenterally. The drugs of choice have been pentavalent antimonials, but they are quite toxic, and failures are increasing due to drug resistance. Important newer therapies are amphotericin B, miltefosine, and paromomycin.

Visceral Leishmaniasis

The treatment of choice for visceral leishmaniasis is liposomal amphotericin B, which is generally effective and well tolerated but very expensive. Liposomal amphotericin B is approved for this use in the United States; other lipid formulations have been less studied. Standard dosing is 3 mg/kg/d intravenously on days 1–5, 14, and 21, but simpler regimens may be equally effective. Infusion-related side effects include gastrointestinal symptoms, fever, chills, dyspnea, hypotension, and hepatic and renal toxicity. Conventional amphotericin B deoxycholate, which is much less expensive, is also highly effective but with more toxicity. It is administered as a slow infusion of 1 mg/kg/d for 20 days or 0.5–1 mg/kg every second day for up to 8 weeks.

Pentavalent antimonials remain the most commonly used drugs to treat leishmaniasis in most areas. Response rates are good outside India, but in India, resistance is a major problem. Two preparations are available, sodium stibogluconate in the United States and many other areas and meglumine antimonate in Latin America and francophone countries; the compounds appear to have comparable activities. In the United States, sodium stibogluconate can be obtained from the CDC Drug Service, Centers for Disease Control and Prevention, Atlanta, GA 30333; telephone: 404-639-3670.

Treatment is given once daily at a dose of 20 mg/kg/d intravenously (preferred) or intramuscularly for 20 days for cutaneous leishmaniasis and 28 days for visceral or mucocutaneous disease. Toxicity increases over time, with development of gastrointestinal symptoms, fever, headache, myalgias, arthralgias, pancreatitis, and rash. Intramuscular injections can cause sterile abscesses. Monitoring should include serial ECGs, and changes are indications for discontinuation to avoid progression to serious arrhythmias.

Miltefosine is the first oral drug for the treatment of leishmaniasis, and it provides excellent results in India, where resistance to antimonials is increasing. It can be administered at a daily oral dose of 2.5 mg/kg in two divided doses for 28 days and was also effective in regimens including a single dose of liposomal amphotericin followed by 7–14 days of miltefosine. A 28-day course of miltefosine (2.5 mg/kg/d) was also effective for the treatment of New World cutaneous leishmaniasis. Vomiting, diarrhea, and elevations in transaminases and kidney function studies are common, but generally short-lived, side effects. Miltefosine is registered for the treatment of visceral leishmaniasis in India and may become the standard of care in that country, although additional study is needed.

Pentamidine isethionate is an alternative therapy for visceral leishmaniasis, given daily or on alternate days for 15 doses of 2–4 mg/kg intramuscularly or intravenously. Side effects include immediate hypotension; tachycardia; and gastrointestinal symptoms during administration; sterile abscesses; and pancreatic, liver, and kidney abnormalities.

Paromomycin showed some success when applied topically to treat cutaneous leishmaniasis and has recently been developed as a parenteral therapy for visceral disease. The drug was shown to be similarly efficacious to amphotericin B in India. It is much less expensive than liposomal amphotericin B or miltefosine. Approval of an intramuscular preparation for visceral leishmaniasis was received in India in 2006. The drug is well tolerated; side effects include ototoxicity and reversible elevations in liver enzymes.

Cutaneous Leishmaniasis

In the Old World, cutaneous leishmaniasis is generally self-healing over some months and does not metastasize to the mucosa, so it may be justified to withhold treatment in regions without mucocutaneous disease if lesions are small and cosmetically unimportant. Lesions on the face or hands are generally treated. New World leishmaniasis has a greater risk of progression to mucocutaneous disease, so treatment is more often warranted. Standard therapy is with pentavalent antimonials for 20 days, as described above. Other treatments include those discussed above for visceral disease, azole antifungals, and allopurinol. Topical therapy has included intralesional antimony, paromomycin ointment, cryotherapy, local heat, and surgical removal. Diffuse cutaneous leishmaniasis and related chronic skin processes generally respond poorly to therapy.

Mucocutaneous Leishmaniasis

Cutaneous infections from regions where parasites include those that cause mucocutaneous disease (eg, *L braziliensis* in parts of Latin America) should all be treated to help prevent disease progression. Treatment of mucocutaneous disease with antimonials is disappointing, with responses in only about 60% in Brazil. Other therapies listed above for visceral leishmaniasis may also be used, although they have not been well studied for this indication.

Prevention & Control

Personal protection measures for avoidance of sand fly bites include use of insect repellants, fine-mesh insect netting, long sleeves and pants, and avoidance of warm shaded areas where flies are common. Disease control measures include destruction of animal reservoir hosts, mass treatment of humans in disease-prevalent areas, residual insecticide spraying in dwellings, limiting contact with dogs and other domesticated animals, and use of permethrin-impregnated collars for dogs.

Malaria

Essentials of Diagnosis

- Residence or exposure in a malaria-endemic area.
- Intermittent attacks of chills, fever, and sweating.
- Headache, malaise, myalgia, nausea, vomiting, splenomegaly; anemia, thrombocytopenia.
- Intraerythrocytic parasites identified in thick or thin blood smears.
- Severe complications of falciparum malaria: cerebral malaria, severe anemia, hypotension, noncardiogenic pulmonary edema, acute kidney failure, hypoglycemia, acidosis, and hemolysis.

General Considerations

Malaria is the most important parasitic disease of humans, causing hundreds of millions of illnesses and probably over a million deaths each year. The disease is endemic in most of the tropics, including much of South and Central America, Africa, the Middle East, the Indian subcontinent, Southeast Asia, and Oceania. Transmission, morbidity, and mortality are greatest in Africa, where most deaths from malaria are in young children. Malaria is also common in travelers from nonendemic areas to the tropics.

Four species of the genus *Plasmodium* classically cause human malaria. *Plasmodium falciparum* is responsible for nearly all severe disease. It is endemic in most malarious areas and is by far the predominant species in Africa. *Plasmodium vivax* is about as common as *P falciparum,* except in Africa. P vivax uncommonly causes severe disease, although this outcome may be more common than previously appreciated. *Plasmodium ovale* and *Plasmodium malariae* are much less common causes of disease, and generally do not cause severe illness. *Plasmodium knowlesi*, a parasite of macaque monkeys, is now recognized to cause occasional illnesses, including some severe disease, in humans in Southeast Asia.

Malaria is transmitted by the bite of infected female anopheline mosquitoes. During feeding, mosquitoes inject sporozoites, which circulate to the liver, and rapidly infect hepatocytes, causing asymptomatic liver infection. Merozoites are subsequently released from the liver, and they rapidly infect erythrocytes to begin the asexual erythrocytic stage of infection that is responsible for human disease. Multiple rounds of erythrocytic development, with production of merozoites that invade additional erythrocytes, lead to large numbers of circulating parasites and clinical illness. Some erythrocytic parasites also develop into sexual gametocytes, which are infectious to mosquitoes, allowing completion of the life cycle and infection of others.

Malaria may uncommonly be transmitted from mother-to-infant (congenital malaria), by blood transfusion, and in nonendemic areas by mosquitoes infected after biting infected immigrants or travelers. In *P vivax* and *P ovale,* parasites also form dormant liver hypnozoites, which are not killed by most drugs, allowing subsequent relapses of illness after initial elimination of erythrocytic infections (see illustration); (see illustration). For all plasmodial species, parasites may recrudesce following initial clinical improvement after suboptimal therapy.

Fig.

Developmental stages of *Plasmodium vivax*, *P ovale*, *P malariae*, and *P falciparum*. (Reproduced, with permission, from Goldsmith R, Heyneman D [editors]: *Tropical Medicine and Parasitology*. Originally

Fig.

Life cycle of *Plasmodium vivax* , the agent of vivax (tertian) malaria. The female *Anopheles* mosquito, shown in the typical biting angle, injects sporozoites into the human bloodstream. ***1–3: Exoerythrocytic phase of asexual division (schizogony)*** . Within an hour, the sporozoites enter liver cells to initiate the exoerythrocytic phase. Penetration of a hepatocyte is followed by growth and multiplication within a few days (2a), or the parasite may become a hypnozoite, with development delayed for as long as 1–2 years. Asexual multiplication fills the enlarging infected liver cell with merozoites (2a). The cell then ruptures, releasing thousands of parasites (3) to initiate either a second hepatic generation or the erythrocytic phase. ***4–9: Erythrocytic phase of schizogony*** . Invasion of the bloodstream and penetration of red blood cells initiate the blood phase of schizogony. Penetration of the red blood cell may begin as a surface or appliqué (accolé) form (4), after which it enters the cell, rounds up, and ingests hemoglobin to form the ring stage (5), which enlarges and becomes an ameboid trophozoite, with numerous cytoplasmic granules (Schüffner's dots) (6) produced as a by-product of hemoglobin breakdown. Nuclear division follows (7), eventually filling the infected cell as the parasites' cytoplasm surrounds each nucleus (8), rupturing it to release more merozoites (9) about 48 hours after onset of the red cell infection (tertian cycle). This asexual erythrocytic schizogony repeats itself with a 48-hour synchronous periodicity. ***10a, 10b: Gametogony*** . Some sporozoites give rise to sexual parasites, gametocyte-producing merozoites that form male (microgametocyte) (10a) or female (macrogametocyte) stages (10b). When taken up in another *Anopheles* mosquito blood meal, the asexual forms are killed but the sexual stages quickly complete gamete formation. ***11–13:*** Fertilization. "Exflagellation" is the release of male microgametes, which scatter, find a female macrogamete, and fuse. The zygote elongates, becomes a motile ookinete (13), and travels to the mosquito's stomach wall. ***14–16: Sporogony*** . In the stomach wall of the mosquito, the ookinete becomes an oocyst (14). Masses of these oocysts may cover the mosquito's stomach. The oocyst nucleus divides innumerable times (15), and the progeny develop into elongated sporozoites, a process termed sporogony. The oocysts rupture (16), passing sporozoites throughout the female body. Most eventually concentrate in the salivary glands, after which the mosquito becomes infective and can initiate a new malaria cycle. (Reproduced, with permission, from Goldsmith R, Heyneman D [editors]: *Tropical Medicine and Parasitology*. Originally published by Appleton & Lange. Copyright © 1989 by The McGraw-Hill Companies, Inc.)

In highly endemic regions, where people are infected repeatedly, antimalarial immunity prevents severe disease in most older children and adults. However, young children, who are relatively nonimmune, are at high risk for severe disease from *P falciparum* infection, and this population is responsible for most deaths from malaria. Pregnant women are also at increased risk for severe falciparum malaria. In areas with lower endemicity, individuals of all ages commonly present with uncomplicated or severe malaria. Travelers, who are generally nonimmune, are at high risk for severe disease from falciparum malaria at any age.

Clinical Findings

Symptoms and Signs

An acute attack of malaria typically begins with a prodrome of headache and fatigue, followed by fever. A classic malarial paroxysm includes chills, high fever, and then sweats. Patients may appear to be remarkably well between febrile episodes. Fevers are usually irregular, especially early in the illness, but without therapy may become regular, with 48-hour cycles (*P vivax* and *P ovale*) or 72-hour cycles (*P malariae*), especially with non-falciparum disease. Headache, malaise, myalgias, arthralgias, cough, chest pain, abdominal pain, anorexia, nausea, vomiting, and diarrhea are common. Seizures may represent simple febrile convulsions or evidence of severe neurologic disease. Physical findings may be absent or include signs of anemia, jaundice, splenomegaly, and mild hepatomegaly. Rash and lymphadenopathy are not typical in malaria, and thus suggestive of another cause of fever. When treated appropriately, uncomplicated malaria generally responds well, with a mortality of about 0.1%.

In the developed world, it is imperative that all persons with suggestive symptoms, in particular fever, who have traveled in an endemic area be evaluated for malaria. The risk for falciparum malaria is greatest within 2 months of return from travel; other species may cause disease many months—and occasionally more than a year—after return from an endemic area.

Severe malaria is principally a result of *P falciparum* infection because this species uniquely infects erythrocytes of all ages and mediates the sequestration of infected erythrocytes in small blood vessels, thereby evading clearance of infected erythrocytes by the spleen. Severe falciparum malaria can include dysfunction of any organ system, including neurologic abnormalities progressing to alterations in consciousness, repeated seizures, and coma (cerebral malaria); severe anemia; hypotension and shock; noncardiogenic pulmonary edema and the acute respiratory distress syndrome; acute kidney injury due to acute tubular necrosis or, less commonly, severe homolysis); hypoglycemia; acidosis; hemolysis with jaundice; hepatic dysfunction; retinal hemorrhages and other fundoscopic abnormalities; bleeding abnormalities, including disseminated intravascular coagulation; and secondary bacterial infections, including pneumonia and *Salmonella* bacteremia. The most common causes of death in children are cerebral malaria and severe anemia; the former a consequence of a single severe infection and the latter often of multiple malarial infections, intestinal helminths, and nutritional deficiencies. Pregnant women are at particular risk during their first pregnancy, probably due to the selection of *P falciparum* strains that preferentially sequester in the placenta; multiparous women are more likely to have antibodies against these strains and thus avoid severe disease. Malaria in pregnancy also increases the likelihood of poor pregnancy outcomes, with increased prematurity, low birth weight, and mortality.

Uncommon disorders resulting from immunologic responses to chronic infection are massive splenomegaly and, with *P malariae* infection, immune complex glomerulopathy with nephrotic syndrome. Although the presentation of malaria is not as markedly affected by HIV infection as are classic opportunistic infections, HIV-infected individuals are at increased risk for malaria and for severe disease, in particular with advanced immunodeficiency.

Laboratory Findings

Giemsa-stained blood smears remain the mainstay of diagnosis (Plates 112, 113, 114, and 115), although other routine stains (eg, Wright stain) will also demonstrate parasites. Thick smears provide efficient evaluation of large volumes of blood, but thin smears are simpler for inexperienced personnel and better for discrimination of parasite species. Single smears are usually positive in infected individuals, although parasitemias may be very low in nonimmune individuals. If illness is suspected, repeating smears in 8- to 24-hour intervals is appropriate. The severity of malaria correlates only loosely with the quantity of infecting parasites, but high parasitemias (especially > 10–20% of erythrocytes infected or > 200,000–500,000 parasites/mcL) or the presence of malarial pigment (a breakdown product of hemoglobin) in > 5% of neutrophils are associated with a particularly poor prognosis.

A second means of diagnosis is rapid diagnostic tests to identify circulating plasmodial antigens with a simple "dipstick" format. These tests are not yet well standardized but are increasingly available around the world, including in the United States. At best, they offer sensitivity and specificity near that of high-quality blood smear analysis and are simpler to perform.

Serologic tests indicate history of disease but are not useful for diagnosis of acute infection. PCR is highly sensitive but not available for routine diagnosis. In immune populations, highly sensitive tests, such as PCR, have limited value because subclinical infections, which are of uncertain significance and not routinely treated, are common.

Other diagnostic findings with uncomplicated malaria include thrombocytopenia, anemia, leukocytosis or leukopenia, liver function abnormalities, and hepatosplenomegaly. Severe malaria can present with the laboratory abnormalities expected for the advanced organ dysfunction discussed above.

Treatment

Malaria is the most common cause of fever in much of the tropics and in travelers seeking medical attention after return from endemic areas. Fevers are often treated presumptively in endemic areas, but ideally, treatment should follow definitive diagnosis, especially in nonimmune individuals.

Symptomatic malaria is caused only by the erythrocytic stage of infection. Available antimalarial drugs (Table 35–2) act against this stage, except for primaquine, which acts principally against hepatic parasites.

Table 35–2. Major antimalarial drugs.

Drug	**Class**	**Use**
Chloroquine	4-Aminoquinoline	Treatment and chemoprophylaxis of infection with sensitive parasites
Amodiaquine[1]	4-Aminoquinoline	Treatment of *Plasmodium falciparum*,

		optimally in fixed combination with artesunate
Piperaquine[1]	4-Aminoquinoline	Treatment of *P falciparum* in fixed combination with dihydroartemisinin
Quinine	Quinoline methanol	Oral and intravenous[1] (for severe infections) treatment of *P falciparum*
Quinidine	Quinoline methanol	Intravenous therapy of severe infections with *P falciparum*
Mefloquine	Quinoline methanol	Chemoprophylaxis and treatment of infections with *P falciparum*
Primaquine	8-Aminoquinoline	Radical cure and terminal prophylaxis of infections with *Plasmodium vivax* and *Plasmodium*

		ovale; alternative for malaria chemoprophylaxis
Sulfadoxine-pyrimethamine (Fansidar)	Folate antagonist combination	Treatment of *P falciparum, optimally in combination with artesunate*
Atovaquone-proguanil (Malarone)	Quinone-folate antagonist combination	Treatment and chemoprophylaxis of *P falciparum* infection
Doxycycline	Tetracycline	Treatment (with quinine) of infections with *P falciparum*; chemoprophylaxis
Halofantrine[1]	Phenanthrene methanol	Treatment of infections with some chloroquine-resistant *P falciparum*
Lumefantrine	Amyl alcohol	Treatment of *P falciparum* malaria in fixed combination with

		artemether (Coartem)
Artemisinins (Artesunate, artemether, dihydroartemisinin)	Sesquiterpene lactone endoperoxides	Treatment of *P falciparum* in oral combination regimens for uncomplicated disease and parenterally for severe malaria

Uncomplicated Falciparum Malaria

Decisions about how to treat malaria are affected by the potential for drug resistance, especially with *P falciparum;* the high cost and limited availability of newer agents for developing world populations; and potential toxicity. The drug sensitivity of individual strains can be determined, but such testing is slow and not useful clinically. Rather, therapeutic decisions are made based on the infecting species and geography. *P falciparum* is now commonly resistant to chloroquine and sulfadoxine-pyrimethamine in most areas, with the principal exceptions of Central America west of the Panama Canal and Hispaniola. Falciparum malaria from other areas should not be treated with these older drugs, and decisions regarding appropriate chemoprophylaxis should follow the same geographic considerations.

In the developing world, malaria is often treated with suboptimal regimens due to the high cost and limited supplies of newer agents. Chloroquine is still widely used in Africa, and its poor efficacy may be underappreciated due to its antipyretic properties, the ability of some immune individuals to recover from acute malaria without effective therapy, and the fact that recrudescences may not lead to symptoms until weeks after partially effective therapy. Sulfadoxine-pyrimethamine is slower acting than most other agents, and suffers from increasing resistance in most areas. Antimalarial therapy in the developing world has undergone major change in recent years, with increasing advocacy of combination regimens as first-line therapies. Most of these regimens are combinations of highly potent but short-acting artemisinin derivatives with longer-acting partner drugs. The World Health Organization (WHO) currently lists five combination therapies as desirable treatments for falciparum malaria in most areas (Table 35–3), but the efficacy of these regimens varies. Other combination therapies are under development. Another drug that remains generally effective for falciparum malaria is quinine, but it must be taken for an extended period to cure disease and is quite poorly tolerated. Thus, in the developing world, quinine is generally reserved for the treatment of severe malaria and for treatment after another regimen has failed.

Table 35–3. Modified WHO recommendations for the treatment of malaria.

Regimen	**Notes**
Artemether-lumefantrine (Coartem, Riamet)	Coformulated, first-line therapy in multiple African countries. Approved in the United States.
Artesunate-amodiaquine (ASAQ)	Coformulated, first-line therapy in multiple African countries.
Artesunate-mefloquine	Standard therapy in parts of Southeast Asia.
Artesunate-sulfadoxine-pyrimethamine	Efficacy low compared with other regimens in most areas.
Amodiaquine-sulfadoxine-pyrimethamine	Less expensive; efficacy varies, but remains good in some areas; recommended as an interim option when efficacy established and other regimens are not available
Dihydroartemisinin-	Newer coformulated

piperaquine	combination. Highly effective in most areas, but not yet part of WHO recommendations.

World Health Organization: Guidelines for the Treatment of Malaria. World Health Organization. Geneva 2006. *ISBM* 924 1546948.

In developed countries, malaria is an uncommon but potentially life-threatening infection of travelers and immigrants, many of whom are nonimmune, so they are at risk for rapid progression to severe disease. Nonimmune individuals with falciparum malaria should generally be admitted to the hospital due to risks of rapid progression of disease. Options for the treatment of uncomplicated falciparum malaria in the United States have increased with the approval of artemether-lumefantrine in 2008; this drug will likely become the standard for this indication (Table 35–4).

Table 35–4. Treatment of malaria.

Clinical Setting	**Drug Therapy**[1]	**Alternative Drugs**
Chloroquine-sensitive	Chloroquine phosphate, 1 g,	

Plasmodium falciparum and *Plasmodium malariae* infections	followed by 500 mg at 6, 24, and 48 hoursor–Chloroquine phosphate, 1 g at 0 and 24 hours, then 0.5 g at 48 hours	
Plasmodium vivax and *Plasmodium ovale* infections	Chloroquine (as above), then (if G6PD normal) primaquine, 30 mg base daily for 14 days	
Uncomplicated infections with chloroquine-resistant *P falciparum*	Coartem (artemether 20 mg, lumefantrine 120 mg), four tablets twice daily for 3 days Malarone, four tablets (total of 1 g atovaquone, 400 mg proguanil) daily for 3 days	Mefloquine, 15 mg /kg once or 750 mg, then 500 mg in 6–8 hours or– ASAQ[2] (artesunate 100 mg, amodiaquine 270 mg), two tablets daily for 3 days

	Quinine sulfate, 650 mg three times daily for 3–7 days Plus one of the following (when quinine given for < 7 days)– Doxycycline, 100 mg twice daily for 7 days or– Clindamycin, 600 mg twice daily for 7 days	
Severe or complicated infections with *P falciparum*[3]	Artesunate 2.4 mg/kg IV every 12 hours for 1 day, then daily[3,6]	Quinidine gluconate,[4–6] 10 mg/kg IV over 1–2 hours, then 0.02 mg/kg IV/min or– Quinidine gluconate,[4–6] 15 mg/kg IV over 4

		hours, then 7.5 mg/kg IV over 4 hours every 8 hours or– Quinine dihydrochloride,[2,4–6] 20 mg/kg IV over 4 hours, then 10 mg/kg IV every 8 hours or– Artemether,[2,6] 3.2 mg/kg IM, then 1.6 mg/kg/d IM

[1] All dosages are oral and refer to salts unless otherwise indicated. See text for additional information on all agents, including toxicities and cautions. See Centers for Disease Control and Prevention's guidelines (phone: 800-CDC-INFO; http://www.cdc.gov) for additional information and pediatric dosing.

[2] Not available in the United States.

[3] Available in the United States only on an investigational basis through the CDC (phone: 770-488-7788).

[4] Cardiac monitoring should be in place during intravenous administration of quinidine or quinine.

[5] Avoid loading doses in persons who have received quinine, quinidine, or mefloquine in the prior 24 hours.

[6] With all parenteral regimens, change to an oral regimen (most commonly doxycycline in adults or clindamycin in children) as soon as the patient can tolerate it.

G6PD, glucose-6-phosphate dehydrogenase.

Modified, with permission, from Katzung BG. *Basic & Clinical Pharmacology*. 11th edition. McGraw-Hill, 2009.

Treatment of Non-Falciparum Malaria

The first-line drug for non-falciparum malaria remains chloroquine. Resistance of *P vivax* to chloroquine has increased, but the drug remains generally effective, and since non-falciparum malaria is uncommonly severe, it is reasonable to accept a small risk of treatment failure. For *P vivax* or *P ovale*, eradication of erythrocytic parasites with chloroquine should be accompanied by treatment with primaquine (after evaluating for glucose-6-phosphate dehydrogenase (G6PD) deficiency; see below) to eradicate dormant liver stages (hypnozoites), which may lead to relapses with recurrent erythrocytic infection and malaria symptoms after weeks to months if left untreated. *P malariae* infections need only be treated with chloroquine.

Treatment of Severe Malaria

Severe malaria can be defined as presentation with any signs of severe illness or organ dysfunction (including prostration, impaired consciousness, convulsions, respiratory distress, shock, acidosis, severe anemia, excessive bleeding, hypoglycemia, jaundice, hemoglobinuria, or kidney impairment) or a high parasite load (generally peripheral parasitemia > 5% or > 200,000 parasites/mcL). It is a medical emergency. Indications for parenteral treatment include severe malaria, as defined above, and inability to take oral drugs. With appropriate prompt therapy and supportive care, rapid recoveries may be seen in even very ill individuals.

In the developing world, severe malaria and deaths from the disease are mostly in young children, in particular from cerebral malaria, severe anemia, and pulmonary disease. In the developed world, mortality from malaria is mostly in adults, and often follows extended illnesses and secondary complications long after eradication of the malarial infection. Standard therapy for severe malaria has been intravenous quinine in most areas and, in the United States, intravenous quinidine, which is equally effective. However, the standard of care is now changing, since intravenous artesunate has shown superiority over quinine.

Patients receiving intravenous quinine or quinidine should receive continuous cardiac monitoring; if QTc prolongation exceeds 25% of baseline, the infusion rate should be reduced. Blood glucose should be monitored every 4–6 hours, and 5–10% dextrose may be coadministered to decrease the likelihood of hypoglycemia. Appropriate care of severe malaria includes maintenance of fluids and electrolytes; respiratory and hemodynamic support; and consideration of blood transfusions, anticonvulsants, antibiotics for bacterial infections, and dialysis. With high parasitemia (> 5–10%), exchange transfusion has been used, but beneficial effects have not clearly been demonstrated, and its role remains uncertain.

Recent studies indicate that intravenous artesunate has superior efficacy and better tolerability than intravenous quinine for severe malaria. Intravenous artesunate became available in the United States in 2007 on an investigational basis through the CDC (for enrollment call 770-488-7788); if approved, the drug is provided emergently from CDC Quarantine Stations. The drug is administered in four doses of 2.4 mg/kg over 3 days, every 12 hours on day 1, and then daily. If artesunate cannot be obtained promptly, severe malaria should be treated with intravenous quinidine. In endemic regions, if parenteral therapy is not available, intrarectal administration of artemether or artesunate is also effective.

Antimalarial Drugs

Chloroquine

Chloroquine remains the drug of choice for the treatment of sensitive *P falciparum* and other species of malaria parasites. Chloroquine is a synthetic 4-aminoquinoline with a very long (1–2 month) terminal elimination half-life. It probably exerts antimalarial activity by concentrating in parasite food vacuoles, preventing biomineralization of the hemoglobin breakdown product heme into hemozoin, and thereby eliciting parasite toxicity due to the buildup of free heme. Chloroquine is active against erythrocytic parasites of all human malaria species. It does not eradicate hepatic stages, so must be used with primaquine to eradicate *P vivax* and *P ovale* infections. Chloroquine-resistant *P falciparum* is widespread in nearly all areas of the world with falciparum malaria, with the exceptions of Central America west of the Panama Canal, Mexico, and Hispaniola. *P falciparum* resistance is mediated principally by mutations in a putative drug transporter, PfCRT. Chloroquine-resistant *P vivax* has been reported from a number of areas, most notably Southeast Asia.

Chloroquine is the drug of choice for the treatment of non-falciparum and sensitive falciparum malaria. It rapidly terminates fever (in 24–48 hours) and clears parasitemia (in 48–72 hours) caused by sensitive parasites. Chloroquine is also the preferred chemoprophylactic agent in malarious regions without resistant falciparum malaria. Eradication of *P vivax* and *P ovale* requires a course of primaquine.

Chloroquine is usually well tolerated, even with prolonged use. Pruritus is common, primarily in Africans. Nausea, vomiting, abdominal pain, headache, anorexia, malaise, blurring of vision, and urticaria are uncommon. Dosing after meals may reduce some adverse events. The long-term administration of chloroquine for rheumatologic diseases can result in irreversible ototoxicity, retinopathy, myopathy, and peripheral neuropathy, but these abnormalities are rarely seen with standard malaria treatment or chemoprophylaxis dosing, even when given for prolonged periods. Parenteral administration can result in severe hypotension, and respiratory or cardiac arrest, and should be avoided.

Amodiaquine and Piperaquine

Amodiaquine is a 4-aminoquinoline that is closely related to chloroquine, and it probably shares mechanisms of action and resistance with that drug. Amodiaquine has been widely used to treat malaria because of its low cost, limited toxicity and, in some areas, effectiveness against chloroquine-resistant strains of *P falciparum*. Use of amodiaquine decreased after recognition of rare but serious side effects, notably agranulocytosis, aplastic anemia, and hepatotoxicity. However, serious side effects are rare with short-term use, and amodiaquine is increasingly advocated as a replacement for chloroquine, particularly in combination regimens (Table 35–3). Chemoprophylaxis with amodiaquine is best avoided because of its apparent increased toxicity with long-term use.

Piperaquine is another 4-aminoquinoline that was previously heavily used in China and has been coformulated with dihydroartemisinin in a new artemisinin-based therapy. Piperaquine appears to be well tolerated, to have minimal problems with resistance (despite prior reports of resistance in China), and in combination with dihydroartemisinin to offer a highly efficacious therapy for falciparum malaria.

Mefloquine

Mefloquine is effective therapy for many chloroquine-resistant strains of *P falciparum* and against other malarial species. Although toxicity is a concern, mefloquine is also a recommended chemoprophylactic drug. Mefloquine is a 4-quinoline methanol that, like chloroquine, has a long half-life, allowing weekly dosing for chemoprophylaxis. Resistance to mefloquine has been reported sporadically from many areas, but it appears to be uncommon except in regions of Southeast Asia with high rates of multidrug resistance (especially border areas of Thailand). Mefloquine resistance appears to be associated with resistance to quinine and halofantrine but not with resistance to chloroquine.

For treatment of uncomplicated malaria, mefloquine is rapidly active and can be administered as a single dose or in two doses over 1 day. It is used in combination with artesunate in Southeast Asia, where resistance to mefloquine has been seen but the combination remains effective in most areas. It should be taken with meals and swallowed with a large amount of water. For chemoprophylaxis, mefloquine is effective against most strains of *P falciparum* and probably all other malarial species. It is recommended by the CDC for chemoprophylaxis in all malarious areas except those with no chloroquine resistance (where chloroquine is preferred) and some rural areas of Southeast Asia with a high prevalence of mefloquine resistance. As with chloroquine, eradication of *P vivax* and *P ovale* requires a course of primaquine.

Adverse effects with weekly dosing of mefloquine for chemoprophylaxis include nausea, vomiting, dizziness, sleep and behavioral disturbances, epigastric pain, diarrhea, abdominal pain, headache, and rash. Despite anecdotal reports of seizures and psychosis, a number of controlled studies have found the frequency of serious adverse effects from mefloquine to be no higher than that with other common chemoprophylactic regimens. Nonetheless, mefloquine should be avoided in persons with histories of psychiatric disease or seizures.

Adverse effects are much more common (up to 50% of treatments) with the higher dosages of mefloquine required for treatment. These effects may be lessened by splitting administration of the drug into two doses separated by 6–8 hours. Serious neuropsychiatric toxicities (depression, confusion, acute psychosis, or seizures) have been reported in less than 1 in 1000 treatments, but some authorities believe that these are more common. Mefloquine can also alter cardiac conduction, and so it should not be coadministered with quinine, quinidine, or halofantrine, and caution is required if quinine or quinidine is used to treat malaria after mefloquine chemoprophylaxis. Mefloquine is generally considered safe in young children and pregnant women.

Quinine and Quinidine

Quinine dihydrochloride and quinidine gluconate remain first-line therapies for falciparum malaria, especially severe disease, although toxicity concerns complicate therapy. Quinine is derived from the bark of the cinchona tree, a traditional remedy for intermittent fevers from South America. The alkaloid quinine was purified from the bark in 1820, and it has been used in the treatment and prevention of malaria since that time. Quinine acts rapidly against the four species of human malaria parasites. Quinidine, the dextrorotatory stereoisomer of quinine, is at least as effective as quinine in the treatment of severe falciparum malaria. After oral administration, quinine is rapidly absorbed, reaching peak plasma levels in 1–3 hours, with a half-life of about 12 hours. Quinidine has a shorter half-life. It is not active against liver stage parasites. The mechanism of action of quinine is unknown.

Resistance of *P falciparum* to quinine is common in some areas of Southeast Asia, where the drug may fail if used alone to treat falciparum malaria. However, quinine still provides at least a partial therapeutic effect in most patients.

Quinine and quinidine are effective treatments for severe falciparum malaria, although intravenous artesunate is becoming the standard of care (see Artemisinins section below). Quinine can be administered slowly intravenously or, in a dilute solution, intramuscularly, but parenteral quinine is not available in the United States, where quinidine is used. The drugs can be administered in divided doses or by continuous intravenous infusion; treatment should begin with a loading dose to rapidly achieve effective plasma concentrations. Intravenous quinine and quinidine should be administered with cardiac monitoring because of their cardiac toxicity and the relative unpredictability of their pharmacokinetics. Therapy should be changed to oral quinine as soon as the patient has improved and can tolerate oral medications.

In areas without newer combination regimens, oral quinine sulfate is appropriate first-line therapy for uncomplicated falciparum malaria, although poor tolerance may limit compliance. Quinine is commonly used with a second drug (most often doxycycline) to shorten the duration of use (usually to 3 days) and to limit toxicity. Therapeutic dosages of quinine and quinidine commonly cause tinnitus, headache, nausea, dizziness, flushing, and visual disturbances, a constellation of symptoms termed "cinchonism." Mild symptoms of cinchonism do not warrant the discontinuation of therapy. Hypersensitivity reactions include rash, urticaria, angioedema, and bronchospasm. Hematologic abnormalities include hemolysis (especially with G6PD deficiency), leukopenia, agranulocytosis, and thrombocytopenia. Therapeutic doses may cause hypoglycemia through stimulation of insulin release; this is a particular problem in severe infections and in pregnant patients, who have increased sensitivity to insulin. Quinine can stimulate uterine contractions, especially in the third trimester, but this effect is mild, and quinine and quinidine are considered safe in pregnancy.

Intravenous infusions of the drugs may cause thrombophlebitis. Overly rapid infusions can cause severe hypotension. ECG abnormalities (QT prolongation) are fairly common, especially with quinidine, but dangerous arrhythmias are uncommon when the drugs are administered appropriately in a monitored setting. Blackwater fever is a rare severe illness, probably due to hypersensitivity, that includes marked hemolysis and hemoglobinuria in the setting of quinine therapy for malaria. Quinine should not be given concurrently with mefloquine and should be used with caution in a patient who has previously received mefloquine. Absorption may be blocked by aluminum-containing antacids. Quinine can raise plasma levels of warfarin and digoxin. Dosage must be reduced in renal insufficiency.

Primaquine

Primaquine phosphate, a synthetic 8-aminoquinoline, is the drug of choice for the eradication of dormant liver forms of *P vivax* and *P ovale.* It is well absorbed orally, reaching peak plasma levels in 1–2 hours, with a plasma half-life of 3–8 hours. Primaquine is active against hepatic stages of all human malaria parasites. This action is optimal soon after therapy with chloroquine or quinine. Primaquine also acts against erythrocytic stage parasites, although this activity is too weak for the treatment of active disease, and against gametocytes. The mechanism of antimalarial action is unknown.

For *P vivax* and *P ovale* infections, chloroquine is used to eradicate erythrocytic forms, and if the G6PD level is normal, a 14-day course of primaquine is initiated to eradicate liver hypnozoites and prevent a subsequent relapse. Some strains of *P vivax*, particularly in New Guinea and Southeast Asia, are relatively resistant to primaquine. For this reason, the CDC has recently doubled the recommended dosage for primaquine to eradicate liver forms (to 52.6 mg primaquine phosphate, or 30 mg base/day), but it remains possible that liver forms may not be eradicated by a single treatment.

Standard chemoprophylaxis does not prevent a relapse of *P vivax* or *P ovale* infections, since the hypnozoite forms of these parasites are not eradicated by chloroquine or other standard treatments. To diminish the likelihood of relapse, some authorities advocate the use of a treatment course of primaquine after the completion of travel to an endemic area.

Primaquine has also been studied as a daily chemoprophylactic agent. Daily treatment with 0.5 mg/kg of base (to a maximum of 30 mg/day) provides protection against malaria caused by *P falciparum* and *P vivax*, but should only be used in persons with documented normal levels of G6PD. In addition, potential toxicities of long-term use remain a concern, and primaquine is not a first-line choice for this purpose.

Primaquine in recommended doses is generally well tolerated. It infrequently causes nausea, epigastric pain, abdominal cramps, and headache, especially when taken on an empty stomach. Rare adverse effects include leukopenia, agranulocytosis, leukocytosis, and cardiac arrhythmias. Standard doses of primaquine may cause hemolysis or methemoglobinemia (manifested by cyanosis), especially in persons with G6PD deficiency or other hereditary metabolic defects. Patients should be tested for G6PD deficiency before primaquine is prescribed. When a patient is deficient in G6PD, treatment strategies may consist of (1) withholding therapy and treating subsequent relapses, if they occur, with chloroquine; (2) treating patients with standard dosing, paying close attention to their hematologic status; or (3) treating with weekly primaquine (45 mg base) for 8 weeks. G6PD-deficient individuals of Mediterranean and Asian ancestry are most likely to have severe deficiency, while those of African ancestry usually have a milder biochemical defect. This difference can be taken into consideration in choosing a treatment strategy. Primaquine should be discontinued if there is evidence of hemolysis or anemia and should be avoided in pregnancy.

Inhibitors of Folate Synthesis

Inhibitors of two parasite enzymes involved in folate metabolism, dihydrofolate reductase (DHFR) and dihydropteroate synthase (DHPS), are used, generally in combination regimens, for the treatment and prevention of malaria. These include the DHFR inhibitors pyrimethamine, proguanil, and chlorproguanil, and the DHPS inhibitors sulfadoxine and dapsone. All described antifolates act relatively slowly against erythrocytic forms of susceptible strains of all four human malaria species. They are not reliably effective against hepatic stages or gametocytes. Fixed-dosed antifolate combinations to treat malaria are sulfadoxine-pyrimethamine (Fansidar) and chloroproguanil/dapsone (Lapdap). These drugs will be discussed only as combinations, as they are not otherwise used to treat or prevent malaria. Malarone, a combination of proguanil with atovaquone, is discussed below.

Fansidar is a fixed combination of sulfadoxine (500 mg) and pyrimethamine (25 mg). Its components reach peak plasma levels within 2–8 hours, with average half-lives of about 170 hours for sulfadoxine and 90 hours for pyrimethamine. The long half-lives of its components allow weekly dosing for chemoprophylaxis, but due to rare serious side effects with long-term dosing, this drug is no longer recommended for this purpose. Sulfadoxine-pyrimethamine became a common back-up drug after chloroquine in many malaria-endemic areas, and replaced chloroquine as the first-line therapy in a number of countries. Advantages of sulfadoxine-pyrimethamine include ease of administration (a single oral dose) and low cost. However, resistance to sulfadoxine-pyrimethamine, which is mediated by a series of point mutations in the target enzymes, is rapidly limiting its efficacy. In addition, it is not reliably effective in *P vivax* infections, and its usefulness against *P ovale* and *P malariae* infections has not been adequately studied, limiting its utility outside of Africa.

Sulfadoxine-pyrimethamine is a component of two combination regimens for uncomplicated malaria recommended by the WHO (Table 35–3). Sulfadoxine-pyrimethamine plus artesunate has shown efficacy in some areas but is best replaced by more effective combination regimens in most areas. Amodiaquine plus sulfadoxine-pyrimethamine has shown surprisingly good efficacy in many parts of Africa, despite increasing resistance to both components, and probably offers the most practical treatment for uncomplicated malaria in many endemic areas without access to artemisinin-based therapies.

Lapdap, a fixed combination of chlorproguanil (80 mg) and dapsone (100 mg), was developed as an inexpensive treatment of falciparum malaria for Africa, and a combination with artesunate was under development. However, the drug was withdrawn in 2008 due to unacceptable rates of hematologic toxicity.

Artemisinins

Artemisinin (qinghaosu) is a sesquiterpene lactone endoperoxide, the active component of an herbal medicine that has been used as an antipyretic in China for over 2000 years. Analogs have been synthesized to increase solubility and improve antimalarial efficacy. The most important of these analogs are artesunate, artemether, and dihydroartemisinin. Artemisinin and its analogs are rapidly absorbed, with peak plasma levels occurring in 1–2 hours and half-lives of 1–3 hours after oral administration. Artesunate and artemether are rapidly metabolized to the active metabolite dihydroartemisinin. A number of artemisinins are available in many countries, although they are more expensive than older therapies. The WHO is encouraging availability of oral artemisinins only in coformulated combination regimens.

Artemisinins act very rapidly against all erythrocytic-stage human malaria parasites. They have no effect on hepatic stages. Artemisinin resistance is not yet an important problem, but *P falciparum* isolates with diminished in vitro susceptibility to artemether have been described from South America, and delayed clearance of parasites has been seen after treatment with artesunate in parts of Cambodia. The antimalarial activity of artemisinins may result from the production of free radicals that follows the iron-catalyzed cleavage of the artemisinin endoperoxide bridge in the parasite food vacuole or inhibition of a parasite calcium ATPase.

Artemisinins are playing an increasing role in the treatment of malaria, including multidrug-resistant *P falciparum* malaria. However, due to their short plasma half-lives, recrudescence rates are unacceptably high after short-course therapy, and they are best used in conjunction with another agent. Also because of their short-half lives, they are not useful in chemoprophylaxis.

Artemisinins should be used for uncomplicated malaria in combination regimens including a longer-acting partner drug, known as artemisinin-based combination therapy. Artesunate plus mefloquine has demonstrated excellent efficacy against multidrug resistant parasites in Thailand, but this regimen is too expensive for widespread use in Africa and other areas. The artemisinin-based combination regimens that are currently most advocated in Africa are artesunate plus amodiaquine (ASAQ) and artemether plus lumefantrine (Coartem), each of which is available as a coformulated product and is the recommended therapy for uncomplicated malaria in a number of countries in Africa. However, implementation of treatment guidelines has been slowed due to the high cost of the new therapies, limited drug availability, and other factors. A third available coformulated regimen that has performed well in clinical trials is dihydroartemisinin plus piperaquine.

In studies of severe malaria, intramuscular artemether was at least as effective as intramuscular quinine, and intravenous artesunate was superior to intravenous quinine in terms of efficacy and tolerability. Thus, the standard of care for severe malaria is intravenous artesunate, when it is available, although parenteral quinine remains an acceptable alternative. Artesunate and artemether have also been effective in the treatment of severe malaria when administered rectally, offering a valuable treatment modality when parenteral therapy is not available.

Artemisinins appear to be very well tolerated. The most commonly reported adverse effects have been nausea, vomiting, and diarrhea, which may often be due to acute malaria, rather than drug toxicity. Irreversible neurotoxicity has been seen in animals after very high doses, but this problem has not been recognized in humans after widespread use. Artemisinins are teratogenic in animals, and they should be avoided in the first trimester of pregnancy for uncomplicated malaria. However, for severe malaria, for which all available treatments entail some risk, the WHO endorses the use of intravenous artesunate or quinine while additional data are gathered on artesunate safety.

Atovaquone plus proguanil (Malarone)

Atovaquone, a hydroxynaphthoquinone, is not effective when used alone, due to rapid development of drug resistance. However, Malarone, a fixed combination of atovaquone (250 mg) and proguanil (100 mg), is highly effective for both the treatment and chemoprophylaxis of falciparum malaria, and it is approved for both indications in the United States. It also appears to be active against other species of malaria parasites. Atovaquone is heavily protein-bound and has a half-life of 2–3 days. It appears to act by disrupting mitochondrial electron transport. Proguanil is an inhibitor of DHFR, as described above. Unlike most other antimalarials, Malarone provides activity against both erythrocytic and hepatic stage parasites.

For treatment, Malarone is given at an adult dose of four tablets daily for 3 days. For chemoprophylaxis, Malarone must be taken daily. It has an advantage over mefloquine and doxycycline in requiring shorter periods of treatment before and after the period at risk for malaria transmission, due to activity against liver-stage parasites, but it is more expensive than the other agents. It should be taken with food.

Malarone is generally well tolerated. Adverse effects include abdominal pain, nausea, vomiting, diarrhea, headache, and rash, and these are more common with the higher dose required for treatment. Reversible elevations in liver enzymes have been reported. The safety of atovaquone in pregnancy is unknown. Plasma concentrations of atovaquone are decreased about 50% by coadministration of tetracycline or rifampin.

Antibiotics

A number of antibacterials in addition to the folate antagonists and sulfonamides are slow-acting antimalarials. They may inhibit protein synthesis or other functions in two plasmodial prokaryote-like organelles, the mitochondrion and the apicoplast. None of the antibiotics should be used as single agents for the treatment of malaria due to their slow rate of action.

Tetracycline and doxycycline are active against asexual erythrocytic forms of all human malaria parasites. They are not active against liver stages. Doxycycline is commonly used in the treatment of falciparum malaria in conjunction with quinidine or quinine, allowing a shorter and better-tolerated course of those drugs. Doxycycline is also a standard chemoprophylactic drug, especially for use in areas of Southeast Asia with high rates of resistance to other antimalarials, including mefloquine. Doxycycline side effects include gastrointestinal symptoms, candidal vaginitis, and photosensitivity. The drug should be taken while upright with a large amount of water to avoid esophageal irritation. Its safety in long-term chemoprophylaxis has not been extensively evaluated.

Clindamycin can be used in conjunction with quinine or quinidine in those for whom doxycycline is not recommended, such as children and pregnant women. The most common toxicities with clindamycin are gastrointestinal. Azithromycin also has antimalarial activity and is now under study for treatment and chemoprophylaxis.

Halofantrine and Lumefantrine

Halofantrine hydrochloride, a phenanthrene-methanol related to quinine, is effective against erythrocytic (but not other) stages of all four human malaria species. Oral absorption is variable and is enhanced with food. Because of toxicity concerns, it should not be taken with meals. Halofantrine is rapidly effective against most chloroquine-resistant strains of *P falciparum*, but its use is limited by irregular absorption and cardiac toxicity. Cross-resistance with mefloquine may occur. As treatment for falciparum malaria, halofantrine is given orally in three 500-mg doses at 6-hour intervals, and this course is repeated in 1 week for nonimmune individuals. Halofantrine is generally well tolerated. The most common adverse effects are abdominal pain, diarrhea, vomiting, cough, rash, headache, pruritus, and elevated liver enzymes. Of greater concern, the drug alters cardiac conduction, with dose-related prolongation of QT and PR intervals. This effect is worsened by prior mefloquine therapy. Rare instances of dangerous arrhythmias and some deaths have been reported. The drug is contraindicated in patients with cardiac conduction defects and should not be used in those who have recently taken mefloquine. It is also contraindicated in pregnancy.

Lumefantrine, an aryl alcohol related to halofantrine, is available only as a fixed-dose combination with artemether (Coartem or Riamet). The half-life of lumefantrine, when used in combination, is 4.5 hours. As with halofantrine, oral absorption is highly variable and improved when the drug is taken with food. Use of Coartem with a fatty meal is recommended. Coartem is highly effective for the treatment of falciparum malaria, but it is expensive and requires twice-daily dosing. Despite these limitations, due to its reliable efficacy against falciparum malaria, Coartem has recently been selected as the first-line therapy for malaria in many African countries. Coartem is well tolerated; side effects include headache, dizziness, loss of appetite, gastrointestinal symptoms, and palpitations. Importantly, Coartem does not appear to cause the cardiac toxicity seen with halofantrine.

Prevention

Malaria is transmitted by night-biting anopheline mosquitoes. Measures to prevent malaria include control of mosquitoes using ecologic measures and insecticides, and optimal use of these modalities is now under study. Bed nets, in particular nets treated with permethrin insecticides, are heavily promoted as inexpensive means of antimalarial protection, and improvement in mortality rates has been demonstrated. Extensive efforts are also underway to develop a malaria vaccine, and partial protection of African children has been demonstrated, but a vaccine offering complete protection is not anticipated in the near future.

When travelers from nonendemic to endemic countries are counseled on the prevention of malaria, it is imperative to emphasize measures to prevent mosquito bites (insect repellents, insecticides, and bed nets), since parasites are increasingly resistant to multiple drugs and no chemoprophylactic regimen is fully protective. Chemoprophylaxis is recommended for all travelers from nonendemic regions to endemic areas, although risks vary greatly for different locations, and some tropical areas entail no risk; specific recommendations for travel to different locales are available from the CDC (www.cdc.gov). Current recommendations from the CDC include the use of chloroquine for chemoprophylaxis in the few areas with only chloroquine-sensitive malaria parasites (principally the Caribbean and Central America west of the Panama Canal), mefloquine or Malarone for most other malarious areas, and doxycycline for areas with a high prevalence of multidrug-resistant falciparum malaria (principally parts of Southeast Asia) (Table 35–5). Recommendations should be checked regularly (Phone: 877-FYI-TRIP; Internet: www.cdc.gov/travel/) because they may change in response to changing resistance patterns and increasing experience with new drugs. In some circumstances, it may be appropriate for travelers to not use chemoprophylaxis but to carry supplies of drugs with them in case a febrile illness develops and medical attention is unavailable. Regimens for self-treatment include artemisinin-based combinations, Malarone, and quinine. Most authorities do not recommend routine terminal chemoprophylaxis with primaquine to eradicate dormant hepatic stages of *P vivax* and *P ovale* after travel, but this may be appropriate in some circumstances, especially for travelers with major exposure to these parasites.

Table 35–5. Drugs for the prevention of malaria in travelers.[1]

Drug	**Use**[2]	**Adult Dosage (All Oral)**[3]
Chloroquine	Areas without resistant *Plasmodium falciparum*	500 mg weekly

Malarone	Areas with multidrug-resistant *P falciparum*	1 tablet (250 mg atovaquone/100 mg proguanil) daily
Mefloquine	Areas with chloroquine-resistant *P falciparum*	250 mg weekly
Doxycycline	Areas with multidrug-resistant *P falciparum*	100 mg daily
Primaquine[4]	Terminal prophylaxis of *Plasmodium vivax* and *Plasmodium ovale* infections; alternative for *P falciparum* prophylaxis	30 mg base daily for 14 days after travel

[1] Recommendations may change, as resistance to all available drugs is increasing. See text for additional information on toxicities and cautions. For additional details and pediatric dosing, see Centers for Disease Control and Prevention's guidelines (phone: 800-CDC-INFO; http://www.cdc.gov). Travelers to remote areas should consider carrying effective therapy (see text) for use if a febrile illness develops, and they cannot reach medical attention quickly.

[2] Areas without known chloroquine-resistant *P falciparum* are Central America west of the Panama Canal, Haiti,

Dominican Republic, Egypt, and most malarious countries of the Middle East. Malarone or mefloquine is currently recommended for other malarious areas except for border areas of Thailand, where doxycycline is recommended.

[3] For drugs other than primaquine, begin 1–2 weeks before departure (except 2 days before for doxycycline and Malarone) and continue for 4 weeks after leaving the endemic area (except 1 week for Malarone). All dosages refer to salts unless otherwise indicated.

[4] Screen for glucose-6-phosphate dehydrogenase deficiency before using primaquine.

Regular chemoprophylaxis is not a standard management practice in developing world populations due to the expense and potential toxicities of long-term therapy. However, there is increasing interest in intermittent preventive therapy, whereby at-risk populations receive antimalarial therapy at certain intervals. This strategy may decrease the incidence of malarial morbidity and mortality while allowing antimalarial immunity to develop. Intermittent preventive therapy has been best studied with sulfadoxine-pyrimethamine, a long-acting drug that is administered in a single dose. The two high-risk populations that have been studied are pregnant women and infants. During pregnancy, sulfadoxine-pyrimethamine provided once during both the second and third trimesters has improved pregnancy outcomes. In infants, intermittent therapy with sulfadoxine-pyrimethamine has offered benefits, but dosing schedules are not standardized. With increasing resistance to sulfadoxine-pyrimethamine, it is not clear if the drug will retain prophylactic efficacy or if other drugs with shorter half-lives will be effective for intermittent preventive therapy.

When to Refer

Referral to an expert on infectious diseases or travel medicine is important with all cases of malaria in the United States, and in particular for falciparum malaria, as management can be complex, but referral should not lead to a delay in initial diagnosis and therapy, since delays in therapy can lead to severe illness or death.

When to Admit

- Non-falciparum malaria generally does not cause severe disease and responds well to therapy, and so admission is only warranted if a patient presents with specific problems that require hospital management.
- Patients with falciparum malaria are generally admitted because the disease can progress rapidly to

severe illness; exceptions may be made with individuals who are from malaria-endemic areas, and thus expected to have a degree of immunity, who are without evidence of severe disease, and who are judged able to return promptly for medical attention if their disease progresses.

Babesiosis

Essentials of Diagnosis

- History of tick bite or exposure to ticks.
- Fever, flu-like symptoms, anemia.
- Intraerythrocytic parasites on Giemsa-stained blood smears.
- Positive serologic tests.

General Considerations

Babesiosis is an uncommon intraerythrocytic infection caused mainly by two *Babesia* species and transmitted by *Ixodes* ticks. In Europe, where only 31 cases of babesiosis have been reported, infection is caused by *Babesia divergens*, which also infects cattle. In the United States, hundreds of cases of babesiosis have been reported, and infection is caused by *Babesia microti*, which also infects wild mammals. Most babesiosis in the United States occurs in the coastal northeast, with some cases also in the upper midwest, following the geographic range of the vector *Ixodes scapularis*, and Lyme disease and anaplasmosis, which are spread by the same vector. Rare episodes of illnesses caused by *B microti*, *B divergens*, and other *Babesia*-like organisms have been reported from other areas. Babesiosis can also be transmitted by blood transfusion.

Clinical Findings

Symptoms and Signs

With *B microti* infections, symptoms appear 1 week to several weeks after a tick bite; parasitemia is evident after 2–4 weeks. Patients usually do not recall the tick bite. The typical flu-like illness develops gradually and is characterized by fever, fatigue, headache, arthralgia, and myalgia. Other findings may include nausea, vomiting, abdominal pain, sore throat, depression, emotional lability, anemia, thrombocytopenia, and splenomegaly. Parasitemia may continue for months to years, with or without symptoms, and the disease is usually self-limited. Severe complications are most likely to occur in older persons or in those who have had splenectomy. Serious complications include respiratory failure, hemolytic anemia, disseminated intravascular coagulation, congestive heart failure, and acute kidney injury. In a study of hospitalized patients, the mortality rate was 6.5%. Most recognized *B divergens* infections in Europe have been in patients who have had splenectomy. These infections progress rapidly with high fever, severe hemolytic anemia, jaundice, hemoglobinuria, and acute kidney injury, with death rates over 40%.

Laboratory Findings

Identification of the intraerythrocytic parasite on Giemsa-stained blood smears establishes the diagnosis (Plate 116). These can be confused with malaria parasites, but the morphology is distinctive. Repeated smears are often necessary because well under 1% of erythrocytes may be infected, especially early in infection, although parasitemias can exceed 10%. An indirect immunofluorescent antibody test for *B microti* is available from the CDC; antibody is detectable within 2–4 weeks after the onset of symptoms and persists for months. Diagnosis can also be made by PCR or by inoculation of hamsters or gerbils.

Plate 116

Treatment

Most patients have a mild illness and recover without therapy. Standard therapy is a 7-day course of quinine

(650 mg orally three times daily) plus clindamycin (600 mg orally three times daily). An alternative is a 7-day course of atovaquone (750 mg orally every 12 hours) plus azithromycin (600 mg orally once daily). Exchange transfusion has been used successfully in severely ill asplenic patients and those with parasitemia greater than 10%.

Toxoplasmosis

Essentials of Diagnosis

- Infection confirmed by isolation of *Toxoplasma gondii* or identification of tachyzoites in tissue or body fluids.

Primary Infection

- Fever, malaise, headache, sore throat.
- Lymphadenopathy.
- Positive IgG and IgM serologic tests.

Congenital Infection

- Follows acute infection of seronegative women and leads to CNS abnormalities and retinochoroiditis.

Infection in Immunocompromised Persons

- Reactivation leads to encephalitis, retinochoroiditis, pneumonitis, myocarditis.
- Positive IgG but negative IgM serologic tests.

General Considerations

T gondii, an obligate intracellular protozoan, is found worldwide in humans and in many species of animals and birds. The definitive hosts are cats. Humans are infected after ingestion of cysts in raw or undercooked meat, ingestion of oocysts in food or water contaminated by cats, transplacental transmission of trophozoites or, rarely, direct inoculation of trophozoites via blood transfusion or organ transplantation. *Toxoplasma* seroprevalence varies widely. It has decreased in the United States to about 20–30%, but it is much higher in other countries in both the developed and developing worlds, where it may exceed 80% (see illustration).

Fig.

Life cycle of *Toxoplasma gondii* . Following ingestion of an infected mouse by a cat, bradyzoites are released from a cyst (1). ***2–7: Enteric stages*** . These consist of a free zoite stage (2), possibly the development of microgametes (3), fertilization by ingestion of a macrogamete (4), formation of an oocyst (5), and development of a free unsporulated oocyst (6), which is shed in the feces of the cat and which sporulates (7) when exposed to oxygen. ***8–11:*** Stages 8–11 occur in intermediate hosts such as mammals and birds: an excysting oocyst in the gut (8), multiplying tachyzoites (9), a free zoite (10), and a cyst containing numerous bradyzoites (11)—resting stages that readily infect cats or other intermediate hosts. Clinical Findings

Symptoms and Signs

The clinical manifestations of toxoplasmosis may be grouped into four syndromes.

Primary Infection in the Immunocompetent Person

After ingestion, *T gondii* infection progresses from the gastrointestinal tract to lymphatics, and then dissemination. Most acute infections are asymptomatic. About 10–20% are symptomatic after an incubation period of 1–2 weeks. Acute infections in immunocompetent persons typically present as mild, febrile illnesses that resemble infectious mononucleosis. Nontender cervical or diffuse lymphadenopathy may persist for weeks to months. Systemic findings may include fever, malaise, headache, sore throat, rash, myalgias, hepatosplenomegaly, and atypical lymphocytosis. Rare severe manifestations are pneumonitis, meningoencephalitis, hepatitis, myocarditis, polymyositis, and retinochoroiditis. Symptoms may fluctuate, but most patients recover spontaneously within at most a few months.

Congenital Infection

Congenital transmission occurs as a result of infection, which may be symptomatic or asymptomatic, in a nonimmune woman during pregnancy. Fetal infection follows maternal infection in 30–50% of cases, but this risk varies by trimester: 10–25% during the first, 30–50% during the second, and 60% or higher during the third trimester. In the United States, an estimated 400 to 4000 congenital infections occur yearly. While the risk of fetal infection increases, the risk of severe fetal disease decreases over the course of pregnancy. Early fetal infections commonly lead to spontaneous abortion, stillbirths, or severe neonatal disease, including neurologic manifestations. Neurologic findings can include seizures, psychomotor retardation, deafness, and hydrocephalus. Retinochoroiditis and other sight-threatening eye lesions may develop. Systemic findings include fever or hypothermia, jaundice, vomiting, diarrhea, hepatosplenomegaly, pneumonitis, myocarditis, and rash. Infections later in pregnancy less commonly lead to major fetal problems. Most infants appear normal at birth, but they may have subtle abnormalities and progress to symptoms and signs of congenital toxoplasmosis later in life. Hepatosplenomegaly and lymphadenopathy may develop in the first few months of life; CNS and eye disease often present later. The most common late presentation of congenital toxoplasmosis is retinochoroiditis.

Retinochoroiditis

This manifestation of congenital toxoplasmosis presents weeks to years after congenital infection, commonly in teenagers or young adults. Retinochoroiditis also is seen in persons who acquire infection early in life, and these patients more often present with unilateral disease. Uveitis is also seen. Disease presents with pain, photophobia, and visual changes, usually without systemic symptoms. Signs and symptoms eventually improve, but visual defects may persist. Rarely, progression may result in glaucoma and blindness.

Reactivated Disease in the Immunocompromised Person

Reactivated toxoplasmosis occurs in patients with AIDS, cancer, or those given immunosuppressive drugs. In patients with advanced AIDS, the most common manifestation is encephalitis, with multiple necrotizing brain lesions. The encephalitis usually presents subacutely, with fever, headache, altered mental status, focal neurologic findings, and other evidence of brain lesions. Less common manifestations of toxoplasmosis in patients with AIDS are chorioretinitis and pneumonitis. Chorioretinitis presents with ocular pain and alterations in vision. Pneumonitis presents with fever, cough, and dyspnea. Toxoplasmosis can develop in seronegative recipients of solid organ or bone marrow transplants due to reactivation or transmission of infection. Reactivation also can occur in those with hematologic malignancies or treated with immunosuppressive drugs. Toxoplasmosis is similar to that in individuals with AIDS, but with immunodeficiency due to malignancy or immunosuppressive drugs, pneumonitis and myocarditis are more common. Less commonly, generalized toxoplasmosis in immunocompromised individuals can involve other organ systems.

Diagnostic Testing

Identification of Parasites

Organisms can be seen in tissue or body fluids, although they may be difficult to identify; special staining techniques can facilitate identification. The demonstration of tachyzoites indicates acute infection; cysts may represent either acute or chronic infection. With lymphadenopathy due to toxoplasmosis, examination of lymph nodes usually does not show organisms. Parasite identification can also be made by inoculation of tissue culture or mice. PCR can be used for sensitive identification of organisms in amniotic fluid, blood, CSF, aqueous humor, and bronchoalveolar lavage fluid.

Serologic Diagnosis

Multiple serologic methods are used, including the Sabin-Feldman dye test, enzyme-linked immunosorbent assay (ELISA), indirect fluorescent antibody test, and agglutination tests. IgG antibodies are seen within 1–2 weeks of infection, and usually persist for life. IgM antibodies peak earlier than IgG and decline more rapidly, although they may persist for years. In immunocompromised individuals in whom reactivation is suspected, a positive IgG assay indicates distant infection, and thus the potential for reactivated disease; a negative IgG argues strongly against reactivation toxoplasmosis. With reactivation in immunocompromised persons, IgM tests are generally negative.

During Pregnancy and in Newborns

Conversion from a negative to positive serologic test or rising titers are suggestive of acute infection, but tests are not routinely performed during pregnancy. When pregnant women are screened, negative IgG and IgM assays exclude active infection, but indicate the risk of infection during the pregnancy. The pattern of positive IgG with negative IgM is highly suggestive of chronic infection, with no risk of congenital disease unless the mother is severely immunocompromised. A positive IgM test is concerning for new infection because of the risk of congenital disease. Confirmatory testing should be performed before consideration of treatment or possible termination of pregnancy due to the limitations of available tests. Tests of the avidity of anti-IgG antibodies can be helpful, but a battery of tests is needed for confirmation of acute infection during pregnancy. When acute infection during pregnancy is suspected, PCR of amniotic fluid offers a sensitive assessment for congenital disease; this test should optimally be performed at 18 weeks of gestation. In newborns, positive IgM or IgA antibody tests are indicative of congenital infection, although the diagnosis is not ruled out by a negative test. Positive IgG assays may represent transfer of maternal antibodies without infection of the infant. Organisms may be identified by PCR; smears; or culture of blood, CSF, or tissue.

In Immunocompetent Individuals

Individuals with a suggestive clinical syndrome should be tested for IgG and IgM antibodies. Seroconversion, a 16-fold rise in antibody titer, or an IgM titer > 1:64 are suggestive of acute infection, although false-positive results may occur. Acute infection can also be diagnosed by detection of tachyzoites in tissue, culture of organisms, or PCR of blood or body fluids. Histologic evaluation of lymph nodes can show characteristic morphology, with or without organisms.

In Immunodeficient Individuals

A presentation consistent with toxoplasmic encephalitis warrants imaging of the brain. CT and MRI scans typically show multiple ring-enhancing cerebral lesions, most commonly involving the corticomedullary junction and basal ganglia. MRI is the more sensitive imaging modality. In AIDS patients with a positive IgG serologic test and no recent antitoxoplasma or antiviral therapy, the predictive value of a typical imaging study is about 80%. The other common diagnosis in this setting is CNS lymphoma, which more typically causes a single brain lesion. The differential diagnosis also includes tuberculoma, bacterial brain abscess, fungal abscess, and carcinoma. Diagnosis of CNS toxoplasmosis is most typically made after a therapeutic trial, with clinical and radiologic improvement expected within 2–3 weeks. Definitive diagnosis requires brain biopsy and search for organisms and typical histology. In retinochoroiditis, funduscopic examination shows vitreous inflammatory reaction, white retinal lesions, and pigmented scars. Diagnosis of other clinical entities in immunocompromised individuals is generally based on histology.

Treatment

Approach to Treatment

Therapy is generally not necessary in immunocompetent persons, since primary illness is self-limited. However, for severe, persistent, or visceral disease, treatment for 2–4 weeks may be considered. Treatment is appropriate for primary infection during pregnancy because the risk of fetal transmission or the severity of congenital disease may be reduced. For retinochoroiditis, most episodes are self-limited, and opinions vary on indications for treatment. Treatment is often advocated for episodes with decreases in visual acuity, multiple or large lesions, macular lesions, significant inflammation, or persistence for over a month. Immunocompromised patients with active infection must be treated. For those with transient immunodeficiency, therapy can be continued for 4–6 weeks after cessation of symptoms. For those with persistent immunodeficiency, such as AIDS patients, full therapy for 4–6 weeks is followed by maintenance therapy with lower doses of drugs. Immunodeficient patients who are asymptomatic but have a positive IgG serologic test should receive long-term chemoprophylaxis.

Choice of Drugs

Drugs for toxoplasmosis are active only against tachyzoites, so they do not eradicate infection. Standard therapy is the combination of pyrimethamine (200 mg loading dose, then 50–75 mg (1 mg/kg) orally once daily) plus sulfadiazine (1–1.5 g orally four times daily), with folinic acid (10–20 mg orally once daily) to prevent bone marrow suppression. Patients should be screened for a history of sulfonamide sensitivity (skin rashes, gastrointestinal symptoms, hepatotoxicity). To prevent crystal-induced nephrotoxicity, good urinary output should be maintained; alkalinization with sodium bicarbonate may also be useful. Pyrimethamine side effects include headache and gastrointestinal symptoms. Even with folinic acid therapy, bone marrow suppression may occur; platelet and white blood cell counts should be monitored at least weekly. A first-line alternative to sulfadiazine is clindamycin (600 mg orally four times daily). Other possible alternatives are trimethoprim-sulfamethoxazole or combining pyrimethamine with atovaquone, clarithromycin, azithromycin, or dapsone. Pyrimethamine is not used during the first trimester of pregnancy due to its teratogenicity. Standard therapy for the treatment of acute toxoplasmosis during pregnancy is with spiramycin (1 g orally three times daily until delivery). This therapy is used only to decrease the risk of fetal infection; it reduces the frequency of transmission to the fetus by about 60%. Spiramycin does not cross the placenta, so when fetal infection is documented or for acute infections late in pregnancy (which commonly lead to fetal transmission) treatment with combination regimens as described above is indicated.

Prevention

Prevention of primary infection centers on avoidance of undercooked meat or contact with material contaminated by cat feces, particularly for seronegative pregnant women and immunocompromised persons. For meat, irradiation, cooking to 66 °C, or freezing to –20 °C kills tissue cysts. Thorough cleaning of hands and surfaces is needed after contact with raw meat or areas contaminated by cats. Oocysts passed in cat feces can remain infective for a year or more, but fresh oocysts are not infective for 48 hours. For best protection, litter boxes should be changed daily and soaked in boiling water for 5 minutes. In addition, gloves should be worn when gardening, fruits and vegetables should be thoroughly washed, and ingestion of dried meat should be avoided.

Universal screening of pregnant women for *T gondii* antibodies is conducted in some countries but not the United States. Pregnant women should ideally have their serum examined for IgG and IgM antibody, and those with negative titers should adhere to the prevention measures described above. Seronegative women who continue to have environmental exposure should undergo repeat serologic screening several times during pregnancy.

For immunocompromised individuals, chemoprophylaxis to prevent primary or reactivated infection is warranted. For transplant recipients, pyrimethamine (25 mg daily for 6 weeks) has been used. For advanced AIDS patients and others, chemoprophylaxis with trimethoprim-sulfamethoxazole (one double-strength tablet daily or two tablets three times weekly), used primarily for protection against *Pneumocystis,* is also effective against *T gondii.* Alternatives are pyrimethamine plus either sulfadoxine or dapsone (various regimens). In AIDS patients, chemoprophylaxis can be discontinued if antiretroviral therapy leads to immune reconstitution.

Amebiasis

Essentials of Diagnosis

- Organisms or antigen present in stools or abscess aspirate.
- Positive serologic tests with colitis or hepatic abscess but may represent prior infections.

Mild to Moderate Colitis

- Recurrent diarrhea.

Severe Colitis

- Severe bloody diarrhea with fever, abdominal pain, and tenderness.
- Prostration.
- Progression to hemorrhage or perforation.

Hepatic Abscess

- Fever, abdominal pain.
- Hepatomegaly, hepatic abscess on imaging studies.

General Considerations

The *Entamoeba* complex contains two morphologically identical species: *Entamoeba dispar,* which is avirulent, and *Entamoeba histolytica*, which may be an avirulent intestinal commensal or lead to serious disease. Disease follows penetration of the intestinal wall, resulting in diarrhea, and with severe involvement, dysentery or extraintestinal disease, most commonly liver abscess.

E histolytica infections are present worldwide but are most prevalent in subtropical and tropical areas under conditions of crowding, poor sanitation, and poor nutrition. Of the estimated 500 million persons worldwide infected with *Entamoeba*, most are infected with *E dispar* and an estimated 10% with *E histolytica*. Mortality from invasive *E histolytica* infections is estimated at 100,000 per year (see illustration).

Fig.

Life cycle of *Entamoeba histolytica*. Transmission of infective cysts of this abundant amebic parasite of humans (with pathologic results in 10–20% of infections) may involve fecally contaminated flies, water, fingers, or food. The damage caused by these parasites can involve ulceration of the colon or passage through the intestinal mucosa and spread to other organs. Ingested cysts are acted on by stomach and duodenal enzymes and rapidly excyst. The tetranucleated trophozoite (1) separates into four uninucleated amebae (2), each of which divides mitotically, resulting in eight uninucleated amebulae (3). Occasionally, trophozoites penetrate the mucosa, ingest red blood cells (4), and initiate the ulceration process, which may spread extraintestinally. Normally, the trophozoites multiply in the lumen of the colon and form a commensal colony, feeding on fecal bacteria (5). The trophozoites complete their vegetative phase and begin cyst formation by a process consisting of loss of water and rounding up (6), formation of a central vacuole with chromatoidal particles (7), an early cyst maturation stage with development of typical round-ended chromatoidals (binucleated stage) (8), and final maturation, often completed after passage in the feces, to form the tetranucleated cyst (9), which loses its chromatoidals and becomes infective to humans. (Reproduced, with permission, from Goldsmith R, Heyneman D [editors]: *Tropical Medicine and Parasitology*. Originally published by Appleton & Lange. Copyright © 1989 by The McGraw-Hill Companies, Inc.)

Humans are the only established *E histolytica* host. Transmission occurs through ingestion of cysts from fecally contaminated food or water, facilitated by person-to-person spread, flies and other arthropods as mechanical vectors, and use of human excrement as fertilizer. Urban outbreaks have occurred because of common-source water contamination.

Clinical Findings

Symptoms and Signs

Intestinal Amebiasis

In most infected persons, the organism lives as a commensal, and the carrier is without symptoms. With symptomatic disease, diarrhea may begin within a week of infection, although an incubation period of 2–4 weeks is more common, with gradual onset of abdominal pain and diarrhea. Fever is uncommon. Periods of remission and recurrence may last days to weeks or longer. Abdominal examination may show distention, tenderness, hyperperistalsis, and hepatomegaly. Microscopic hematochezia is common. More severe presentations include colitis and dysentery, with more extensive diarrhea (10–20 stools per day) and bloody stools. With dysentery, physical findings include high fevers, prostration, vomiting, abdominal pain and tenderness, hepatic enlargement, and hypotension. Severe presentations are more common in young children, pregnant women, those who are malnourished, and those receiving corticosteroids. Thus, in endemic regions, corticosteroids should not be started for presumed inflammatory bowel disease without first ruling out amebiasis. Fulminant amebic colitis can progress to necrotizing colitis, intestinal perforation, mucosal sloughing, and severe hemorrhage, with mortality rates over 40%. More chronic complications of intestinal amebiasis include chronic diarrhea with weight loss, which may last for months to years; bowel ulcerations; and amebic appendicitis. Localized granulomatous lesions (amebomas) can present after either dysentery or chronic intestinal infection. Clinical findings include pain, obstructive symptoms, and hemorrhage and may suggest intestinal carcinoma.

Extraintestinal Amebiasis

The most common extraintestinal manifestation is amebic liver abscess. This can occur with colitis, but more frequently presents without history of prior intestinal symptoms. Patients present with the acute or gradual onset of abdominal pain, fever, an enlarged and tender liver, anorexia, and weight loss. Diarrhea is present in a small number of patients. Physical examination may show intercostal tenderness. Abscesses are most commonly single and in the right lobe of the liver, and they are much more common in men. Without prompt treatment, amebic abscesses may rupture into the pleural, peritoneal, or pericardial space, which is often fatal. Amebic infections may rarely occur throughout the body, including the lungs, brain, and genitourinary system.

Laboratory Findings

Laboratory studies with intestinal amebiasis show leukocytosis and hematochezia, with fecal leukocytes not present in all cases. With extraintestinal amebiasis, leukocytosis and elevated liver function studies are seen.

Diagnostic Testing

Diagnosis is by finding *E histolytica* or its antigen or by serologic tests. However, each method has limitations.

Intestinal Amebiasis

Diagnosis is most commonly made by identifying organisms in the stool. *E histolytica* and *E dispar* cannot be distinguished, but the identification of amebic trophozoites or cysts in a symptomatic patient is highly suggestive of amebiasis (see illustration). Stool evaluation for organisms is not highly sensitive (~30–50% for amebic colitis), and at least three stool specimens should be evaluated after concentration and staining. Multiple serologic assays are available; these tests are fairly sensitive, although sensitivity is lower (~70% in colitis) early in illness, and they cannot distinguish recent and old disease, as they remain positive for years after infection. A commercially available stool antigen test (TechLab II) offers improved sensitivity (> 90% for colitis); it requires fresh or frozen (not preserved) stool specimens. PCR-based tests are available but not used routinely. Colonoscopy of uncleansed bowel typically shows no specific findings in mild intestinal disease; in severe disease, ulcers may be found with intact intervening friable mucosa, resembling inflammatory bowel disease (Plate 117). Examination of fresh ulcer exudate for motile trophozoites and for *E histolytica* antigen may yield a diagnosis.

(Reproduced, with permission, from Goldsmith R, Heyneman D [editors]: *Tropical Medicine and Parasitology*. Originally published by Appleton & Lange. Copyright © 1989 by The McGraw-Hill Companies, Inc.)

Hepatic Abscess

Serologic tests for anti-amebic antibodies are almost always positive, except very early in the infection. Thus, a negative test in a suspicious case should be repeated in about a week. The stool *E histolytica* antigen test is positive in ~40% of cases. The TechLab II test can also be used to test serum, with good sensitivity if used before the initiation of therapy. Examination of stools for organisms or antigen is frequently negative. As imaging studies cannot distinguish amebic and pyogenic abscesses, when a diagnosis is not available from serologic studies, percutaneous aspiration may be indicated, ideally with an image-guided needle. Aspiration typically yields brown or yellow fluid. Detection of organisms in the aspirate is uncommon, but detection of *E histolytica* antigen is very sensitive and diagnostic. The key risk of aspiration is peritoneal spillage leading to peritonitis from amebas or other (pyogenic or echinococcal) organisms.

Imaging

Liver abscesses can be identified by ultrasonography, CT, or MRI, typically with round or oval low-density nonhomogeneous lesions, with abrupt transition from normal liver to the lesion, and hypoechoic centers. Abscesses are most commonly single, but more than one may be present. The right lobe is usually involved.

Treatment

Treatment of amebiasis generally entails the use of metronidazole or tinidazole to eradicate tissue trophozoites and a luminal amebicide to eradicate intestinal cysts (Table 35–6). Asymptomatic infection with *E dispar* does not require therapy. This organism cannot be differentiated morphologically from *E histolytica*, but with negative serology *E dispar* colonization is likely, and treatment is not indicated. Colonization with *E histolytica* is generally treated with a luminal agent. Effective luminal agents are diloxanide furoate (500 mg orally three times daily with meals for 10 days), iodoquinol (diiodohydroxyquin; 650 mg orally three times daily for 21 days), and paromomycin (30 mg/kg base orally, maximum 3 g, in three divided doses after meals daily for 7 days). Side effects associated with luminal agents are flatulence with diloxanide furoate, mild diarrhea with iodoquinol, and gastrointestinal symptoms with paromomycin. Relative contraindications are thyroid disease for iodoquinol and kidney disease for iodoquinol or paromomycin.

Table 35–6. Treatment of amebiasis.[1]

Clinical Setting	**Drugs of Choice and Adult Dosage**	**Alternative Drugs and Adult Dosage**
Asymptomatic intestinal infection	Luminal agent: Diloxanide furoate,[2] 500 mg orally three times daily for 10 days	
	or–	
	Iodoquinol, 650 mg orally three times daily for 21 days	
	or–	
	Paromomycin, 10 mg/kg orally three times daily for 7 days	
Mild to moderate intestinal infection	Metronidazole, 750 mg orally three times daily (or 500 mg IV every 6 hours) for 10 days	Luminal agent (see above)plus either–
	or–	Tetracycline, 250 mg

		orally three times daily for 10 days
	Tinidazole, 2 g orally daily for 3 days	or–
	plus–	Erythromycin, 500 mg orally four times daily for 10 days
	Luminal agent (see above)	
Severe intestinal infection	Metronidazole, 750 mg orally three times daily (or 500 mg IV every 6 hours) for 10 days	Luminal agent (see above)
	or–	plus either–
	Tinidazole, 2 g orally daily for 3 days	Tetracycline, 250 mg orally three times daily for 10 days
	plus–	or–
	Luminal agent (see above)	Dehydroemetine [3] or emetine,[2] 1 mg/kg SC or IM for 3–5 days
Hepatic	Metronidazole,	Dehydroemetine [3] or

abscess, ameboma, and other extraintestinal disease	750 mg orally three times daily (or 500 mg IV every 6 hours) for 10 days	emetine,[2] 1 mg/kg SC or IM for 8–10 days, followed by (liver abscess only) chloroquine, 500 mg orally twice daily for 2 days, then 500 mg daily for 21 days
	or–	
	Tinidazole, 2 g orally daily for 3 days	plus–
	plus–	Luminal agent (see above)
	Luminal agent (see above)

[1] See text for additional details and cautions.

[2] Not available in the United States.

[3] Available in the United States only from the CDC Drug Service, Centers for Disease Control and Prevention, Atlanta (404-639-3670).

Treatment of intestinal amebiasis requires metronidazole (750 mg orally three times daily for 10 days) or tinidazole

(2 g orally once daily for 3 days for mild disease and 5 days for serious disease) plus a luminal agent (Table 35–6). Metronidazole has most commonly been used in the United States, but tinidazole, which is now available, offers simpler dosing and less side effects. Metronidazole often induces transient nausea, vomiting, epigastric discomfort, headache, or a metallic taste. A disulfram-like reaction may occur if alcohol is coingested. Drug interactions with cimetidine, some anticoagulants, phenytoin, phenobarbital, lithium, and other drugs have been reported. Metronidazole is carcinogenic in mice; it should be avoided in pregnant or nursing mothers if possible. The same toxicities and concerns probably apply for tinidazole, although it appears to be better tolerated. Fluid and electrolyte replacement is also important for patients with significant diarrhea. Surgical management of acute complications of intestinal amebiasis is best avoided whenever possible. Successful therapy of severe amebic colitis may be followed by postdysenteric colitis, with continued diarrhea without persistent infection; this syndrome generally resolves in weeks to months.

Alternatives for the treatment of intestinal amebiasis are tetracycline (250–500 mg orally four times daily for 10 days) plus chloroquine (500 mg orally daily for 7 days). Emetine or dehydroemetine can be given subcutaneously (preferred) or intravenously in a dose of 1–1.5 mg/kg/d; the maximum daily dose is 90 mg for dehydroemetine and

65 mg for emetine). These agents are effective but cardiotoxic with a narrow therapeutic range and should be used only until severe disease is controlled. They cause nausea, vomiting, and pain at the injection site. Emetine is not available in the United States and dehydroemetine is only available from the Centers for Disease Control and Prevention Drug Service.

Amebic liver abscess is also treated with metronidazole or tinidazole plus a luminal agent (even if intestinal infection is not documented; Table 35–6). Metronidazole can be used intravenously when necessary. With failure of initial response to metronidazole or tinidazole, chloroquine, emetine or dehydroemetine may be added. Needle aspiration may be helpful for large abscesses (over 5–10 cm), in particular if the diagnosis remains uncertain, if there is an initial lack of response, or if a patient is very ill, suggesting imminent abscess rupture. With successful therapy, abscesses disappear slowly (over months).

Prevention & Control

Prevention requires safe water supplies; sanitary disposal of human feces; adequate cooking of foods; protection of foods from fly contamination; handwashing; and, in endemic areas, avoidance of foods that cannot be cooked or peeled. Water supplies can be boiled, treated with iodine (0.5 mL tincture of iodine per liter for 20 minutes; cysts are resistant to standard concentrations of chlorine), or filtered.

Infections with Pathogenic Free-Living Amebas

Essentials of Diagnosis

- Acute meningoencephalitis or chronic granulomatous encephalitis after contact with warm fresh water.
- Keratitis, particularly in contact lens users.

The free-living amebas that cause disease in humans are of the genera *Acanthamoeba, Naegleria,* and *Balamuthia.* The organisms are widely distributed in soil and fresh and brackish water. *Acanthamoeba* and *Naegleria* species have been found to harbor *Legionella, Vibrio cholerae,* and other endosymbiotic bacteria and may serve as a reservoir for these organisms.

Primary Amebic Meningoencephalitis

Primary amebic meningoencephalitis is a fulminating, hemorrhagic, necrotizing meningoencephalitis that occurs in healthy children and young adults and is rapidly fatal. It is caused by free-living amebas, most commonly *Naegleria fowleri*, but also *Balamuthia mandrillaris* and *Acanthamoeba* species. *N fowleri* is a thermophilic organism found in fresh and polluted warm lake water, domestic water supplies, swimming pools, thermal water, and sewers. Most patients give a history of exposure to warm fresh water. The incubation period varies from 2 to 15 days. Early symptoms include headache, fever, stiff neck, and lethargy, often associated with rhinitis and pharyngitis. Vomiting, disorientation, and other signs of meningoencephalitis develop within 1 or 2 days, followed by coma and then death within 7–10 days. No distinctive clinical features distinguish the infection from acute bacterial meningoencephalitis. CSF shows hundred to thousands of leukocytes and erythrocytes per cubic millimeter. Protein is usually elevated, and glucose is normal or moderately reduced. A fresh wet mount of the CSF may show motile trophozoites. Staining with Giemsa or Wright stain will identify the trophozoites. Species identification is based on morphology and immunologic methods. Primary amebic meningoencephalitis is nearly always fatal. Amphotericin B appears to be the drug of choice; one survivor was treated with intravenous and intrathecal amphotericin B, intravenous miconazole, and oral rifampin.

Granulomatous Amebic Encephalitis

Acanthamoeba species and *B mandrillaris* can cause an encephalitis that is more chronic in nature than primary amebic meningoencephalitis. Neurologic disease may be preceded by skin lesions, including ulcers and nodules. After an uncertain incubation period neurologic symptoms develop slowly, with headache, meningismus, nausea, vomiting, lethargy, and low-grade fevers progressing over weeks to months to focal neurologic findings, mental status abnormalities, and eventually coma and death. CT and MRI show single or multiple nonspecific lesions. Lumbar puncture is dangerous due to increased intracranial pressure. CSF shows a lymphocytic pleocytosis with elevated protein; amebas are not typically seen. Diagnosis can be made by biopsy of skin or brain lesions. Information on the treatment of granulomatous amebic encephalitis is limited. Some patients have been successfully treated with various combinations of flucytosine, pentamidine, fluconazole or itraconazole, sulfadiazine, trimethoprim-sulfamethoxazole, and azithromycin.

Acanthamoeba Keratitis

Acanthamoeba keratitis is a painful, sight-threatening corneal infection. It is associated with corneal trauma, most commonly after use of contact lenses and contaminated saline solution. Symptoms include severe eye pain, photophobia, tearing, and blurred vision. The keratitis progresses slowly, with waxing and waning clinical findings over months, and can progress to blindness. Lack of response to antibacterial, antifungal, and antiviral topical treatments and potential use of contaminated contact lens solution are suggestive of the diagnosis. Ocular examination shows corneal ring infiltrates, but these can also be caused by other pathogens. The diagnosis can be made by examination or culture of corneal scrapings. Available diagnostic techniques include examination of a wet preparation for cysts and motile trophozoites, examination of stained specimens, evaluation with immunofluorescent reagents, culture of organisms, and PCR.

Acanthamoeba keratitis can be cured with local therapy. Topical propamidine isethionate (0.1%), chlorhexidine digluconate (0.02%), polyhexamethylene biguanide, neomycin-polymyxin B-gramicidin, miconazole, and combinations of these agents have been used successfully. Oral itraconazole or ketoconazole can be added for deep keratitis. Drug resistance has been reported. Use of corticosteroid therapy is controversial. In some cases, debridement and penetrating keratoplasty have been performed in addition to medical therapy. Corneal grafting can be done after the amebic infection has been eradicated.

Coccidiosis (Cryptosporidiosis, Isosporiasis, Cyclosporiasis, Sarcocystosis) & Microsporidiosis

Essentials of Diagnosis

- Acute diarrhea, especially in children in developing countries.
- Outbreaks of diarrhea secondary to contaminated water or food.
- Prolonged diarrhea in immunocompromised persons.
- Diagnosis mostly by identifying organisms in specially stained stool specimens.

General Considerations

The causes of coccidiosis are *Cryptosporidium* species (*C parvum*, *C hominis*, *and others)*; *Isospora belli; Cyclospora cayetanensis;* and *Sarcocystis* species. Microsporidiosis is caused by at least 14 species, most commonly *Enterocytozoon bieneusi* and *Encephalitozoon intestinalis.* These infections occur worldwide, particularly in the tropics and in regions where hygiene is poor. They are causes of endemic childhood gastroenteritis (particularly in malnourished children in developing countries); institutional and community outbreaks of diarrhea; traveler's diarrhea; and acute and chronic diarrhea in immunosuppressed patients, in particular those with AIDS. They are all notable for the potential to cause prolonged diarrhea, often lasting for a number of weeks. Clustering occurs in households, day care centers, and among sexual partners.

The infectious agents are oocysts (coccidiosis) or spores (microsporidiosis) transmitted from person to person or by contaminated drinking or swimming water or food. Ingested oocysts release sporozoites that invade and multiply in enterocytes, primarily in the small bowel. Coccidian oocysts and microsporidian cysts can remain viable in the environment for years.

I belli and *C cayetanensis* appear to infect only humans. *C cayetanensis* has caused a number of food-borne outbreaks in the United States in recent years, most commonly associated with imported fresh produce. *Sarcocystis* infects many species; humans are intermediate hosts (infected by ingestion of fecal sporocysts) for some species but definitive hosts for *Sarcocystis bovihominis* and *Sarcocystis suihominis* (infected by ingestion of tissue cysts in undercooked beef and pork, respectively).

Cryptosporidiosis is a zoonosis *(C parvum* principally infects cattle), but most human infections are acquired from humans, in particular with *C hominus.* Cryptosporidia are highly infectious and readily transmitted in day care settings and households. They have caused large community outbreaks due to contaminated water supplies (causing ~400,000 illnesses in Milwaukee in 1993) and are the leading cause of recreational water–associated outbreaks of gastroenteritis. Of note, coccidia and microsporidians will generally be missed on routine evaluations of stool for ova and parasites, as they require special staining techniques for identification.

Clinical Findings

Symptoms and Signs

Cryptosporidiosis

The incubation period appears to be about 1–14 days. In developing countries, disease is seen primarily in children under 5 years of age, where cryptosporidiosis causes 5–10% of cases of childhood diarrhea. Presenting symptoms in children include acute watery diarrhea, abdominal pain, and cramps, with rapid resolution in most patients; however, symptoms quite commonly persist for 2 weeks or more. In developed countries, most patients are adults. Diarrhea in immunocompetent individuals typically lasts from 5 to 10 days. It is usually watery, with accompanying abdominal pain and cramps, nausea, vomiting, and fever. Relapses may follow initial resolution of symptoms. Mild illness and asymptomatic infection may also be common.

Cryptosporidiosis is a well-characterized cause of diarrhea in those with AIDS. It was common in this population before the advent of highly active antiretroviral therapy, particularly in those with advanced immunosuppression. Clinical manifestations are variable, but patients commonly have chronic diarrhea with frequent foul smelling stools, malabsorption, and weight loss. Severe, life-threatening watery diarrhea may be seen. Cryptosporidiosis also causes extraintestinal disease with AIDS, including pulmonary infiltrates with dyspnea and biliary tract infection with sclerosing cholangitis and AIDS cholangiopathy.

Isosporiasis

The incubation period for *I belli* is about 1 week. In immunocompetent persons, it usually causes a self-limited watery diarrhea lasting 2–3 weeks, with abdominal cramps, anorexia, malaise, and weight loss. Fever is unusual. Chronic symptoms may persist for months in some patients. In immunocompromised patients, isosporiasis more commonly causes severe and chronic diarrhea, with complications including marked dehydration, malnutrition, and hemorrhagic colitis. Extraintestinal disease has been reported rarely.

Cyclosporiasis

C cayetanensis oocysts must undergo a period of sporulation of 7 days or more after shedding before they become infectious. Therefore, person-to-person spread is unlikely, and spread has typically been due to contaminated food (especially fresh produce) and water. The incubation period is 1–11 days. Infections can be asymptomatic. Cyclosporiasis causes an illness similar to that described for the other pathogens described in this section, with watery diarrhea, abdominal cramps, nausea, fatigue, and anorexia. Fever is seen in 25% of cases. Symptoms typically continue for 2 weeks or longer and may persist for months. Relapses of diarrhea are common. Diarrhea may be preceded by a flu-like prodrome and followed by persistent fatigue. In immunocompromised patients, cyclosporiasis is typically more severe and prolonged, with chronic fulminant watery diarrhea and weight loss.

Sarcocystosis

Sarcocystis infection may be common in some developing countries, but it is usually asymptomatic. Infection appears to most commonly follow the ingestion of undercooked beef or pork, leading to the development of cysts in muscle, with myalgias, fever, bronchospasm, pruritic rash, lymphadenopathy, and subcutaneous nodules. Ingestion of fecal sporocysts may lead to gastrointestinal symptoms.

Microsporidiosis

Microsporidia are obligate intracellular protozoans that cause a wide spectrum of diseases. Many infections are of zoonotic origin, but human-to-human transmission has been documented. Infection is mainly by ingestion of spores, but also by direct inoculation of the eyes. In immunocompetent hosts, microsporidian infections most commonly present as self-limited diarrhea. Ocular infections have also been described. Disease from microsporidia is seen mainly in immunocompromised persons, particularly those with AIDS. Infections in AIDS patients are most commonly with *E bieneusi* and *E intestinalis*. They cause chronic diarrhea, with anorexia, bloating, weight loss, and wasting, especially in those with advanced immunodeficiency. Fever is usually not seen. Other illnesses in immunocompromised persons associated with microsporidians (including the genera *Enterocytozoon*, *Encephalitozoon*, *Brachiola*, *Vittaforma*, *Pleistophora*, *Trachipleistophora*, and *Microsporidium*) include biliary tract disease (AIDS cholangiopathy), genitourinary infection with cystitis, kidney disease, hepatitis, peritonitis, myositis, respiratory infections including sinusitis, central nervous system infections including granulomatous encephalitis, and disseminated infections. Ocular infections with *Encephalitozoon* species cause conjunctivitis and keratitis, presenting as redness, photophobia, and loss of visual acuity.

Laboratory Findings

Cryptosporidiosis

Typically, stool is without blood or leukocytes. Diagnosis is traditionally made by detecting the organism in stool using a modified acid-fast stain; this technique is relatively insensitive, and multiple specimens should be evaluated before ruling out the diagnosis. Of note, routine evaluation for ova and parasites typically does not include a modified acid-fast stain, so this must be specifically requested in many laboratories. Antigen detection offers improved sensitivity and specificity, both of which are well over 90% with a number of available assays, and these methods may now be considered the optimal means of diagnosis.

Isosporiasis

Diagnosis of isosporiasis is by examination of stool wet mounts or after modified acid-fast staining, in which the organism is clearly distinguishable from other parasites. Other stains also show the organism. Shedding of oocysts may be intermittent, so the sensitivity of stool evaluation is not high, and multiple samples should be examined. The organism may also be identified in duodenal aspirates or small bowel biopsies.

Cyclosporiasis

Diagnosis is made by examination of stool wet mounts or after modified acid-fast staining. Multiple specimens may need to be examined to make a diagnosis. The organism can also be identified in small bowel aspirates or biopsy specimens.

Sarcocystosis

Eosinophilia and elevated creatine kinase may be seen. Diagnosis is by identification of the acid-fast organisms in stool or by identification of trophozoites or bradyzoites in tissue biopsies.

Microsporidiosis

Diagnosis can be made by identification of organisms in specially stained stool, fluid, or tissue specimens, for example with Weber chromotrope-based stain. Electron microscopy is helpful for confirmation of the diagnosis and speciation. PCR and culture techniques are available but not used routinely.

Treatment

Most acute infections with these pathogens in immunocompetent persons are self-limited and do not require treatment. Supportive treatment for severe or chronic diarrhea includes fluid and electrolyte replacement and, in some cases, parenteral nutrition.

Cryptosporidiosis

Treatment of cryptosporidiosis is challenging. No agent is clearly effective. Modest benefits have been seen in some (but not other) studies with paromomycin, a non-absorbed aminoglycoside (25–35 mg/kg orally for 14 days has been used), and nitazoxanide (500 mg–1 g orally twice daily for 3 days in nonimmunocompromised and 2–8 weeks in advanced AIDS patients), which is approved in the United States for this indication. It can cause mild gastrointestinal toxicity. Other agents that have been used with mixed success in AIDS patients with cryptosporidiosis include azithromycin, spiramycin, bovine hyperimmune colostrum, and octreotide. Reversing immunodeficiency with effective antiretroviral therapy is of greatest importance.

Isosporiasis

Isosporiasis is effectively treated in immunocompetent and immunosuppressed persons with trimethoprim-sulfamethoxazole (160 mg/800 mg orally 2–4 times daily for 10 days, with higher doses for patients with AIDS). An alternative therapy is pyrimethamine (75 mg orally in four divided doses) with folinic acid (10–25 mg/d orally). Maintenance therapy with low-dose trimethoprim-sulfamethoxazole (daily or three times per week) or Fansidar (weekly) prevents relapse in those with persistent immunosuppression.

Cyclosporiasis

Cyclosporiasis is also treated with trimethoprim-sulfamethoxazole (dosing as for isosporiasis). With AIDS, long-term maintenance therapy (three times weekly) helps prevent relapse. For patients intolerant of trimethoprim-sulfamethoxazole, ciprofloxacin (500 mg orally twice daily for 7 days) showed efficacy, albeit with less ability to clear the organism than trimethoprim-sulfamethoxazole.

Sarcocystosis

For sarcocystosis, no specific treatment is established, but sulfadiazine cleared intestinal cysts in one study.

Microsporidiosis

Treatment of microsporidiosis is complex. Infections with most species, including those causing gastrointestinal and other manifestations, should be treated with albendazole (400 mg orally twice daily for 2–4 weeks), which has activity against a number of species, but relatively poor efficacy (about 50%) against *E bieneusi*, the most common microsporidial cause of diarrhea in AIDS patients. Fumagillin, which is used to treat honeybees and fish with microsporidian infections, has shown benefit in clinical trials at a dose of 20 mg three times per day for 14 days; treatment was accompanied by reversible thrombocytopenia. As with cryptosporidiosis, the best means of controlling microsporidiosis in AIDS patients is to restore immune function with effective antiretroviral therapy. Ocular microsporidiosis can be treated with fumagillin solution (3 mg/mL); this probably should be given with concurrent systemic therapy with albendazole. Adjunctive management may include corticosteroids to decrease inflammation and keratoplasty.

Prevention

Water purification is important for control of these infections. Chlorine disinfection is not effective against cryptosporidial oocysts, so other purification measures are needed. Immunocompromised patients should boil or filter drinking water and should consider avoidance of lakes and swimming pools. Routine precautions (handwashing, gloves, disinfection) should prevent institutional patient-to-patient spread. Optimal means of preventing microsporidial infections are not well understood, but water purification as discussed above and body substance precautions for immunocompromised and hospitalized individuals are likely effective.

Giardiasis

Essentials of Diagnosis

- Acute diarrhea, which may be profuse and watery.
- Chronic diarrhea with greasy, malodorous stools.
- Abdominal cramps, distention, flatulence, and malaise.

- Cysts or trophozoites in stools.

General Considerations

Giardiasis is a protozoal infection of the upper small intestine caused by the flagellate *Giardia lamblia* (also called *Giardia intestinalis* and *Giardia duodenalis*). The parasite occurs worldwide, most abundantly in areas with poor sanitation. In developing countries, young children are very commonly infected. In the United States and Europe, the infection is the most common intestinal protozoal pathogen; the US estimate is of 100,000 to 2.5 million new infections leading to 5000 hospital admissions yearly. Groups at special risk include travelers to *Giardia*-endemic areas, those who swallow contaminated water during recreation or wilderness travel, men who have sex with men, and persons with impaired immunity. Outbreaks are common in households, children's day care centers, and residential facilities, and may occur as a result of contamination of water supplies.

The organism occurs in feces as a flagellated trophozoite and as a cyst. Only the cyst form is infectious by the oral route; trophozoites are destroyed by gastric acidity. Humans are a reservoir for the pathogen; dogs, cats, beavers, and other mammals have been implicated but not confirmed as reservoirs. Under suitable moist, cool conditions, cysts can survive in the environment for weeks to months (see illustration). Cysts are transmitted as a result of fecal contamination of water or food, by person-to-person contact, or by anal-oral sexual contact. The infectious dose is low, requiring as few as ten cysts. After the cysts are ingested, trophozoites emerge in the duodenum and jejunum. Epithelial damage and mucosal invasion are uncommon. Hypogammaglobulinemia, low secretory IgA levels in the gut, achlorhydria, and malnutrition favor the development of infection.

Fig.
Life cycle of *Giardia lamblia* . The infection in humans is usually acquired from ingestion of water or food contaminated with human or animal feces containing viable cysts of the organism. Excystation occurs in the duodenum, and the trophozoites emerge and multiply in the small bowel. ***1–3:*** Typical flattened, bilaterally symmetric trophozoites (1) multiply in the small intestine, usually adhering to the villi by their ventral suckers (inset: note imprint of former attachment site). Encystation occurs in the small bowel or colon (2), and the cysts pass out in the feces (3) and survive for long periods in cold water, ready for transmission to another host. Lange. Copyright © 1989 by The McGraw-Hill Companies, Inc.)

Clinical Findings

Symptoms and Signs

It is estimated that about 50% of infected persons have no discernable infection, about 10% become asymptomatic cyst passers, and 25–50% develop an acute diarrheal syndrome. Acute diarrhea may clear spontaneously but is commonly followed by chronic diarrhea. The incubation period is usually 1–3 weeks but may be longer. The illness may begin gradually or suddenly. Cysts may not be detected in the stool at the onset of the illness. The acute phase may last days or weeks, and is usually self-limited, although cyst excretion may be prolonged. The initial illness may include profuse watery diarrhea, and hospitalization may be required due to dehydration, particularly in young children. Typical symptoms of chronic disease are abdominal cramps, bloating, flatulence, nausea, malaise, and anorexia. Fever and vomiting are uncommon. Diarrhea is usually not severe in the chronic stage of infection; stools are greasy or frothy and foul smelling, without blood, pus, or mucus. The diarrhea may be daily or recurrent; intervening periods may include constipation. Symptoms can persist for weeks to months. Weight loss is frequent. Chronic disease can include malabsorption, including fat- and protein-losing enteropathy and vitamin deficiencies.

Laboratory Findings

Most patients seek medical attention after having been ill for over a week, commonly with weight loss of 5 kg or more. Stool is generally without blood or leukocytes. Diagnosis is traditionally made by the identification of trophozoites or cysts in stool. A wet mount of liquid stool may identify motile trophozoites. Stained fixed specimens may show cysts or trophozoites (see illustration). Sensitivity of stool analysis is not ideal, estimated at 50–80% for a single specimen and over 90% for three specimens. Sampling of duodenal contents with a string test or biopsy is no longer generally recommended, but biopsies may be helpful in very ill or immunocompromised patients. When giardiasis is highly suspected, antigen assays may be simpler and cheaper than repeated stool examinations, but these tests will not identify other stool pathogens. Multiple tests, which identify antigens of trophozoites or cysts, are available. They are generally quite sensitive (85–98%) and specific (90–100%).

Treatment

The treatments of choice for giardiasis are metronidazole (250 mg orally three times daily for 5–7 days) or tinidazole (2 g orally once). The drugs are not universally effective; cure rates for single courses are typically about 80–95%. Toxicities are as described for treatment of amebiasis, but the lower dosages used for giardiasis limit side effects. Nitazoxanide (500 mg orally twice daily for 3 days) is generally well tolerated but may cause mild gastrointestinal side effects. Other drugs with activity against *Giardia* include furazolidone (100 mg orally four times a day for 7 days), which is about as effective as the other named drugs but causes gastrointestinal side effects; albendazole (400 mg orally daily for 5 days), which appears to have similar efficacy but has been less studied; and paromomycin (500 mg orally three times a day for 7 days), which appears to have somewhat lower efficacy but may be the safest drug (considering potential mutagenicity of metronidazole, tinidazole, and furazolidone) in pregnant women. Symptomatic giardiasis should always be treated. Treatment of asymptomatic patients should be considered, since they can transmit the infection to others. With a presumptive diagnosis but negative diagnostic studies, an empiric course of treatment is sometimes appropriate. Household or day care contacts with an index case should be tested and treated if infected.

Prevention

Community chlorination (0.4 mg/L) of water is relatively ineffective for inactivating cysts, so filtration is required. For wilderness or international travelers, bringing water to a boil for 1 minute or filtration with a pore size less than 1 mcm are adequate. In day care centers, appropriate disposal of diapers and frequent hand washing are essential.

Other Intestinal Flagellate Infections

Balantidium coli is a large ciliated intestinal protozoan found worldwide, but particularly in the tropics. Pigs are the main reservoir. The infection is rare in humans, and results from ingestion of cysts passed in stools of humans or swine. In the new host, the cyst wall dissolves and the trophozoite may invade intestinal mucosa, causing abscesses and ulcerations. Many infections are asymptomatic. Chronic infections may cause recurrent diarrhea or dysentery. Deaths have occurred from intestinal perforation and hemorrhage.

Dientamoeba fragilis is a protozoan that commonly causes infection without symptoms, so its role in human disease remains somewhat controversial. Symptoms attributed to the pathogen include diarrhea, abdominal pain, and anorexia. Other flagellates may infect humans, are generally considered nonpathogens, but may be markers for fecal-oral contamination.

Diagnosis of balantidiasis is established by finding trophozoites or cysts in stool, or in ulcer scrapings of the large bowel. *D fragilis* infection can be hard to diagnose because it only exists in the trophozoite form; the sensitivity of evaluation of three stools is 70–90%. The treatment of choice for balantidiasis is tetracycline, 500 mg orally four times daily for 10 days. The alternative is iodoquinol (diiodohydroxyquin), 650 mg orally three times daily for 21 days, and metronidazole, paromomycin, and nitazoxanide have also been used successfully. *D fragilis* infections have been successfully treated with metronidazole, iodoquinol, and tetracycline; all the regimens are the same as for balantidiasis.

Trichomoniasis

Essentials of Diagnosis

- Copious vaginal discharge in women.
- Nongonococcal urethritis in men.
- Motile trichomonads on wet mounts.

General Considerations

Trichomoniasis is caused by the protozoan *Trichomonas vaginalis* and is among the most common sexually transmitted diseases, causing vaginitis in women and nongonococcal urethritis in men. It can also occasionally be acquired by other means, since it can survive in moist environments for several hours.

Clinical Findings

Symptoms and Signs

T vaginalis is often harbored asymptomatically. For women with symptomatic disease, after an incubation period of 5 days to 4 weeks, a vaginal discharge develops, often with vulvovaginal discomfort, pruritus, dysuria, dyspareunia, or abdominal pain. Examination shows a copious discharge, which is usually not foul smelling but is often frothy and yellow or green in color. Inflammation of the vaginal walls and cervix with punctate hemorrhages are common. Most men infected with *T vaginalis* are asymptomatic, but it can be isolated from about 10% of men with nongonococcal urethritis. In men with trichomonal urethritis, the urethral discharge is generally more scanty than with other causes of urethritis.

Diagnostic Testing

Diagnosis is typically made by identifying the organism in vaginal or urethral secretions. Examination of wet mounts will show motile organisms. Tests for bacterial vaginosis (pH > 4.5, fishy odor after addition of potassium hydroxide) are often positive with trichomoniasis. Rapid antigen and nucleic acid amplification tests that are highly specific and much more sensitive than wet mounts are available but are not yet widely used.

Treatment

The treatment of choice is metronidazole (2 g single oral dose). Tinidazole is also approved for this indication at the same dose, and it may be better tolerated and active against some resistant parasites. Toxicities of these drugs are discussed in the section on amebiasis. If the large single dose cannot be tolerated, an alternative metronidazole dosage is 500 mg orally twice daily for 1 week. All infected persons should be treated, even if asymptomatic, to prevent subsequent symptomatic disease and limit spread. Treatment failure suggests reinfection, but metronidazole-resistant organisms have been reported. These may be treated with tinidazole, longer courses of metronidazole, or some experimental therapies.

Schistosomiasis (Bilharziasis)

Essentials of Diagnosis

- History of fresh water exposure in an endemic area.
- Acute schistosomiasis: fever, headache, myalgias, cough, malaise, urticaria, diarrhea, and eosinophilia.
- Intestinal schistosomiasis: abdominal pain, fatigue, diarrhea, and hepatomegaly, progressing to anorexia, weight loss, and features of portal hypertension.
- Urinary schistosomiasis: hematuria and dysuria,

progressing to hydroureter, hydronephrosis, urinary infections, and kidney injury.

- Diagnosis based on characteristic eggs in feces or urine; biopsy of rectal or bladder mucosa; positive serology.

General Considerations

Schistosomiasis, which affects more than 200 million persons worldwide, leads to severe consequences in 20 million persons and about 100,000 deaths annually. The disease is caused by five species of trematode blood flukes. Four species cause intestinal schistosomiasis, with infection of mesenteric venules: *Schistosoma mansoni*, which is present in Africa, the Arabian peninsula, South America, and the Caribbean (see illustration); *Schistosoma japonicum*, which is endemic in China and Southeast Asia (see illustration); *Schistosoma mekongi*, which is endemic near the Mekong River in Southeast Asia; and *Schistosoma intercalatum*, which occurs in parts of Africa. *Schistosoma haematobium* causes urinary schistosomiasis, with infection of venules of the urinary tract, and is endemic in Africa and the Middle East (see illustration). Transmission of schistosomiasis is focal, with greatest prevalence in poor rural areas. Control efforts have diminished transmission significantly in many areas, but high level transmission remains common in sub-Saharan Africa and some other areas. Prevalence of infection and illness typically peaks at about 15–20 years of age.

Humans are infected with schistosomes after contact with fresh water containing cercariae released by infected snails. Infection is initiated by penetration of skin or mucous membranes. After penetration, schistosomulae migrate to the portal circulation, where they rapidly mature. After about 6 weeks, adult worms mate, and migrate to terminal mesenteric or bladder venules, where females deposit their eggs. Some eggs reach the lumen of the bowel or bladder and are passed with feces or urine, while others are retained in the bowel or bladder wall or transported in the circulation to other tissues, in particular the liver (see illustration); (see illustration). Disease in endemic areas is primarily due to a host response to eggs, with granuloma formation and inflammation, eventually leading to fibrosis. Chronic infection can result in scarring of mesenteric or vesicular blood vessels, leading to portal hypertension and alterations in the urinary tract. In previously uninfected individuals, such as travelers with fresh water contact in endemic regions, acute schistosomiasis may occur, with a febrile illness 2–8 weeks after infection.

Fig.

Schistosomiasis. ***Upper panel:*** Schistosomiasis mansoni, causing fibrotic liver damage (A) and polyp formation in the colon (B) from the reaction to antigens secreted and excreted through miracidium-containing eggs (right) that become trapped in these tissues. ***Center panel:*** Schistosomiasis japonicum, in which numerous eggs (right), often laid in clusters, cause granulomatous damage to the liver (C) and gut wall (D), much as with *S mansoni* infection. ***Lower panel:*** Schistosomiasis haematobium, in which organisms located in the bladder plexus and nearby venous blood vessels (E) produce eggs (right) that induce tissue reactions which cause thickening of the bladder wall (F), sometimes associated with bladder cancer. Hydroureter—upper right of inset (E)—is commonly caused by eggs blocking drainage of urine into the bladder. (Reproduced, with permission, from Goldsmith R, Heyneman D [editors]: *Tropical Medicine and Parasitology*. Originally published by Appleton & Lange. Copyright © 1989 by The McGraw-Hill Companies, Inc.)

Fig.

Life cycle of *Schistosoma mansoni* (blood fluke). Contact with water exposes skin to cercarial penetration. Worms mature in the liver and migrate to mesenteric vessels, where females lay eggs that work through into the lumen of the large intestine and pass out in human wastes. Eggs captured in intestinal tissues or liver are encapsulated in a granulomatous response (inset). Susceptible intermediate host snails (*Biomphalaria*) are penetrated by miracidia that hatch from eggs which reach snail-inhabited water. Sporocyst multiplication in the snail results in large numbers of infective cercariae that leave the snail and seek to penetrate human skin. ***1–9:*** The skin is penetrated by a cercaria, which breaks off its forked tail and passes into the dermis through a hair follicle (1). A mature pair of worms in the liver (2) migrates up mesenteric vessels (3) to egg-laying sites near or within villi. The eggs cytolyze or mechanically work their way through villi into the gut lumen (4), enter water with feces (5), and quickly hatch, releasing ciliated miracidia (6) that penetrate a host snail. The penetrating larva passes through two or perhaps several generations of sporocysts (7). Cercariae produced by the final sporocyst generation pass into the water (8) and collect near the surface, suspended by their forked tails (9), awaiting the stimulus of nearby human skin for penetration and onset of a new cycle. (Reproduced, with permission, from Goldsmith R, Heyneman D [editors]: *Tropical Medicine and Parasitology*. Originally published by Appleton & Lange. Copyright © 1989 by The McGraw-Hill Companies, Inc.)

Clinical Findings

Symptoms and Signs

Cercarial Dermatitis

Following cercarial penetration, localized erythema develops in some individuals, which can progress to a pruritic maculopapular rash that persists for some days. Dermatitis can be caused by human schistosomes and, in non-tropical areas, by bird schistosomes that cannot complete their life cycle in humans (swimmer's itch).

Acute Schistosomiasis (Katayama Syndrome)

A febrile illness may develop 2–8 weeks after exposure in persons without prior infection, most commonly after heavy infection with *S mansoni* or *S japonicum.* Presenting symptoms and signs include acute onset of fever; headache; myalgias; cough; malaise; urticaria; diarrhea, which may be bloody; hepatosplenomegaly; lymphadenopathy; and pulmonary infiltrates. Localized lesions may occasionally cause severe manifestations, including CNS abnormalities and death. Acute schistosomiasis usually resolves in 2–8 weeks.

Chronic Schistosomiasis

Many infected persons have light infections and are asymptomatic, but an estimated 50–60% have symptoms and 5–10% have advanced organ damage. Asymptomatic infected children may suffer from anemia and growth retardation. Symptomatic patients with intestinal schistosomiasis typically experience abdominal pain, fatigue, diarrhea, and hepatomegaly. Over years, anorexia, weight loss, weakness, colonic polyps, and features of portal hypertension develop. Late manifestations include hematemesis from esophageal varices, hepatic failure, and pulmonary hypertension. Urinary schistosomiasis may present within months of infection with hematuria and dysuria, most commonly in children and young adults. Fibrotic changes in the urinary tract can lead to hydroureter, hydronephrosis, bacterial urinary infections and, ultimately, kidney disease or bladder cancer.

Laboratory Findings

Microscopic examination of stool or urine for eggs, evaluation of tissue, or serologic tests establish the diagnosis (see illustration). Characteristic eggs can be identified on smears of stool or urine, but filtration or concentration techniques can improve yields. Quantitative tests that yield > 400 eggs per gram of feces or 10 mL of urine are indicative of heavy infections with increased risk of complications. Diagnosis can also be made by biopsy of the rectum, colon, liver, or bladder. Serologic tests include an ELISA available from the CDC that is 99% specific for all species. The test is 99% sensitive for *S mansoni*, 95% sensitive for *S haematobium*, but < 50% sensitive for *S japonicum*. Species-specific immunoblots can increase sensitivity. In acute schistosomiasis, leukocytosis, and marked eosinophilia may occur; serologic tests may become positive before eggs are seen in stool or urine. After therapy, eggs may be shed in stool or urine for months, and so the identification of eggs in fluids or tissue or positive serologic tests cannot distinguish past or active disease. Tests for egg viability are available. With a diagnosis of schistosomiasis, evaluation for the extent of disease is warranted, including liver function studies and imaging of the liver with intestinal disease and ultrasound or other imaging studies of the urinary system in urinary disease (see x-ray).

Treatment

Treatment is indicated for all schistosome infections. In areas where recurrent infection is common, treatment is valuable in reducing worm burdens and limiting clinical complications. The drug of choice for schistosomiasis is praziquantel. The drug is administered for 1 day at an oral dose of 40 mg/kg (in one or two doses) for *S mansoni*, *S haematobium*, and *S intercalatum* infections and a dose of 60 mg/kg (in two or three doses) for *S japonicum* and *S mekongi*. Cure rates are generally > 80% after a single treatment, and those not cured have marked reduction in the intensity of infection. Praziquantel is active against invading cercariae but not developing schistosomulae. Therefore, the drug may not prevent illness when given after exposure and, for recent infections, a repeat course after a few weeks may be appropriate. Praziquantel may be used during pregnancy. Resistance to praziquantel has been reported. Toxicities include abdominal pain, diarrhea, urticaria, headache, nausea, vomiting, and fever, and may be due both to direct effects of the drug and responses to dying worms. Alternative therapies are oxamniquine for *S mansoni* infection and metrifonate for *S haemotobium* infection. Both of these drugs currently have limited availability (they are not available in the United States), and resistance may be a problem. No second-line drug is available for *S japonicum* infections.

The antimalarial drug artemether has activity against schistosomulae and adult worms and may be effective in chemoprophylaxis; however, it is expensive, and long-term use in malarious areas might select for resistant malaria parasites. With severe disease, use of corticosteroids in conjunction with praziquantel may decrease complications. Treatment should be followed by repeat examinations for eggs about every 3 months for 1 year after therapy, with re-treatment if eggs are seen.

Prevention

Travelers to endemic areas should avoid fresh water exposure. Vigorous toweling after exposure may limit cercarial penetration. Chemoprophylaxis with artemether has shown efficacy but is not standard practice. Community control of schistosomiasis includes improved sanitation and water supplies, elimination of snail habitats, and intermittent administration of treatment to limit worm burdens.

Fascioliasis

Infection by *Fasciola hepatica*, the sheep liver fluke, results from ingestion of encysted metacercariae on watercress or other aquatic vegetables. Infection is prevalent in sheep-raising areas in many countries, especially parts of South America, the Middle East, and southern Europe. *Fasciola gigantica* has a more restricted distribution in Asia and Africa and causes similar findings. Eggs are passed from host feces into fresh water, leading to infection of snails, and then deposition of metacercariae on vegetation. In humans, metacercariae excyst, penetrate into the peritoneum, migrate through the liver, and mature in the bile ducts, where they cause local necrosis and abscess formation (see illustration).

Fig.

Life cycles of *Fasciola hepatica* and *F gigantica* (liver flukes). A grazing cow ingests vegetation contaminated with metacercariae. Young flukes excyst, penetrate through the intestine, and pass directly into the liver parenchyma and bile ducts, where maturation of flukes follows. Undeveloped eggs are excreted via bile into stool. If this occurs in marshy or wet areas inhabited by host snails (*Lymnaea*), the miracidia within the eggs develop, hatch, and infect the snails by penetration. In the snail, miracidia become sporocysts that produce rediae which multiply and finally produce swarms of cercariae. These motile larvae emerge, swim from the snail, and encyst on nearby aquatic vegetation. ***1–10:*** After excystation (1), the fluke passes through the gut wall directly into the liver and bile ducts (3). The mature fluke (2) produces large numbers of undeveloped eggs (4) that pass in feces from the host, mature in water (5), hatch, and release miracidia (6) that invade a suitable snail in which multiplication occurs through sporocyst formation and successive generations of rediae (7, 8), resulting finally in shedding from the snail of great numbers of cercariae (9). These swimming larvae encyst on aquatic or immersed vegetation (10), the source of infection of cattle and other herbivores or of humans. (Reproduced, with permission, from Goldsmith R, Heyneman D [editors]: *Tropical Medicine and Parasitology*. Originally published by Appleton & Lange. Copyright © 1989 by The McGraw-Hill Companies, Inc.)

Two clinical syndromes are seen, related to acute migration of worms and chronic infection of the biliary tract. Symptoms related to migration of larvae present 6–12 weeks after ingestion. Typical findings are abdominal pain, fever, malaise, weight loss, urticaria, eosinophilia, and leukocytosis. Tender hepatomegaly and elevated liver function tests may be seen. Rarely, migration to other organs may lead to localized disease. The symptoms of worm migration subside after 2–4 months, followed by asymptomatic infection by adult worms or intermittent symptoms of biliary obstruction, with biliary colic and, at times, findings of cholangitis. Early diagnosis is difficult, as eggs are not found in the feces during the acute migratory phase of infection. Clinical suspicion should be based on clinical findings and marked eosinophilia in at risk individuals. CT and other imaging studies show hypodense migratory lesions of the liver. Serologic assays may be positive about 1 month before eggs are seen in stool, but specificities of available tests are not ideal. Definitive diagnosis is made by the identification of characteristic eggs in stool. Repeated examinations may be necessary. In chronic infection, imaging studies show masses obstructing the extrahepatic biliary tract.

Fascioliasis is unusual among fluke infections, in that it does not respond well to treatment with praziquantel. The treatment of choice is triclabendazole, which is also used in veterinary medicine, but is not available in the United States. Standard dosing of 10 mg/kg orally in a single dose or two doses over 12 hours achieves a cure rate of about 80%, but repeat dosing is indicated if abnormal radiologic findings or eosinophilia do not resolve. The second-line drug for fascioliasis is bithionol (30–50 mg/kg/d orally in three divided doses on alternate days for 10–15 days; available in the United States from the CDC Drug Service, Centers for Disease Control and Prevention, Atlanta, GA 30333; telephone: 404-639-3670). Treatment with either drug can be accompanied by abdominal pain and other gastrointestinal symptoms. Prevention of fascioliasis involves avoidance of ingestion of raw aquatic plants.

Clonorchiasis & Opisthorchiasis

Infection by *Clonorchis sinensis*, the Chinese liver fluke, is endemic in areas of Japan, Korea, China, Taiwan, Southeast Asia, and the far eastern part of Russia. Millions of people are affected and, in some communities, prevalence can reach over 80%. Opisthorchiasis is principally caused by *Opisthorchis felineus* (regions of the former Soviet Union) or *Opisthorchis viverrini* (Thailand, Laos, Vietnam). Clonorchiasis and opisthorchiasis are clinically indistinguishable. Parasite eggs are shed into water in human or animal feces, where they infect snails, which release cercariae, which infect fish. Human infection follows ingestion of raw, undercooked, or pickled freshwater fish containing metacercariae. These parasites excyst in the duodenum and ascend into the biliary tract, where they mature and remain for many years, shedding eggs in the bile (see illustration).

Fig.
Life cycle of *Clonorchis sinensis* (Chinese liver fluke). Ingestion of raw fish infected with viable metacercariae is followed by development of mature flukes in hepatic bile ducts and then passage of fluke eggs in feces with access to water in which the appropriate snail hosts (*Parafossarulus*) are found. A suitable freshwater fish host such as the carp then becomes infected with metacercariae. ***1–10:*** After excystation (1) in the human

duodenum of cysts ingested with raw or undercooked freshwater fish, an adult fluke (2) in the bile duct (3) lays eggs (4) in bile that pass to the intestine and are deposited with stool into a fishpond. Feces are eaten by a snail, and the ingested egg hatches within the snail, releasing a miracidium (5) that penetrates snail tissues and forms a mother sporocyst (6) which produces a number of rediae (7). The rediae proceed through successive generations, ultimately filling much of the snail. The final redial generation produces numbers of large-tailed cercariae (8) that leave the snail, swim to a fish, crawl between its scales (9), and encyst in the tissues (10) to be eaten by another human or piscivorous mammalian reservoir host to sustain the cycle. (Reproduced, with permission, from Goldsmith R, Heyneman D [editors]: *Tropical Medicine and Parasitology*. Originally published by Appleton & Lange. Copyright © 1989 by The McGraw-Hill Companies, Inc.)

Most patients harbor few parasites and are asymptomatic. An acute illness can occur 2–3 weeks after initial infection, with fever, abdominal pain, tender hepatomegaly, urticaria, and eosinophilia. The acute syndrome is difficult to diagnose, since ova may not appear in the feces until 3–4 weeks after onset of symptoms. In chronic heavy infections, findings include abdominal pain, anorexia, weight loss, and tender hepatomegaly. More serious findings can include recurrent bacterial cholangitis and sepsis, cholecystitis, liver abscess, and pancreatitis (see micrograph). An increased risk of cholangiocarcinoma has been documented.

Fig.

Opisthorchis viverrini in the bile duct. Cross section of biliary duct through the portal triad near the capsule, showing an adult *O viverrini* with eggs in the uterus. Note dilated and tortuous thickening of the duct with proliferated epithelial lining. x 100. (Courtesy of M Riganti.)

Early diagnosis is presumptive, based on clinical findings and epidemiology. Subsequent diagnosis is made by finding characteristic eggs in stool or duodenal or biliary contents (see illustration); (see illustration). Repeated concentration tests of stool may be necessary. Imaging studies show characteristic biliary tract dilatations with filling defects due to flukes. Serologic tests can be helpful but are limited by suboptimal specificity.

The drug of choice is praziquantel. A dosage of 25 mg/kg orally three times daily for 2 days provides cure rates over 95%. One day of treatment may be sufficient. Re-treatment may be required, especially in some areas with known decreased praziquantel efficacy. The second-line drug is albendazole (400 mg orally twice daily for 7 days), which appears to be somewhat less effective.

Paragonimiasis

Eight species of *Paragonimus* lung flukes cause human disease. The most important is *Paragonimus westermani*. *Paragonimus* species are endemic in East Asia, Oceania, West Africa, and South America, where millions of persons are infected. Eggs are released into fresh water, where parasites infect snails, and then cercariae infect crabs and crayfish. Human infection follows consumption of raw, undercooked, or pickled freshwater shellfish. Metacercariae then excyst, penetrate into the peritoneum, and pass into the lungs, where they mature into adult worms over about 2 months (see illustration).

Fig.

Life cycle of *Paragonimus westermani* (lung fluke). Ingestion of cysts in uncooked freshwater crab or crayfish meat is followed by excystation of juvenile worms in the duodenum and migration to the lungs, where they form worm pairs enclosed in host tissue. Eggs from adult worms are passed to the environment in sputum or stool and develop in the shell. Miracidia hatch and penetrate an appropriate snail (*Semisulcospira*). Massive multiplication of rediae occurs in the snail, which in turn produces many cercariae that leave the snail and crawl on the bottom of a pond in search of a crustacean intermediate host. ***1–11:*** Metacercariae (1) in crab tissue undergo excystation (2) in the human duodenum; (3) and (4) show an adult worm in the lung and a cross section of a worm pair in a lung capsule. Undeveloped eggs (5) are carried to the mouth, swallowed, and passed in stool. Hatching of a miracidium (6) in suitable fresh water after development in the eggshell is followed by penetration of a snail by the miracidium, which changes into a mother sporocyst (7) in snail tissue. Rediae leave the sporocyst and initiate successive generations of redial progeny (8), which fill the snail. Cercariae emerge from the final redial generation (9) and move along the bottom of the pond, using an adhesive substance in a round bunny tail, toward an intermediate host, which they penetrate, aided by a penetration stylet (10, 11), whereupon a metacercaria encysts in the flesh of a crab. (Reproduced, with permission, from Goldsmith R, Heyneman D [editors]: *Tropical Medicine and Parasitology*. Originally published by Appleton & Lange. Copyright © 1989 by The McGraw-Hill Companies, Inc.)

Most persons have moderate worm burdens and are asymptomatic. In symptomatic cases, abdominal pain and diarrhea develop 2 days to 2 weeks after infection, followed by fever, cough, chest pain, urticaria, and eosinophilia. Acute symptoms may last for several weeks. Chronic infection can cause cough productive of brown sputum, hemoptysis, dyspnea, and chest pain, with progression to chronic bronchitis, bronchiectasis, bronchopneumonia, lung abscess, and pleural disease. Ectopic infections can cause disease in other organs, most commonly the CNS, where disease can present with seizures, headaches, and focal neurologic findings due to parasite meningitis, and intracerebral lesions.

The diagnosis of paragonimiasis is made by identifying characteristic eggs in sputum or stool or identifying worms in biopsied tissue (see illustration); (see illustration). Multiple examinations and concentration techniques may be needed. Serologic tests may be helpful; an ELISA available from the CDC has sensitivity and specificity > 95%. Chest radiographs may show varied abnormalities of the lungs or pleura, including infiltrates, nodules, cavities, and fibrosis, and the findings can be confused with those of tuberculosis. With CNS disease, skull radiographs can show clusters of calcified cysts, and CT or MRI can show clusters of ring-enhancing lesions.

Treatment is with praziquantel (25 mg/kg orally three times daily for 2 days), which provides efficacy of at least 90%. Alternative therapies are bithionol and triclabendazole. As with cysticercosis, for cerebral paragonimiasis, praziquantel should generally be used with corticosteroids. Chronic infection may lead to permanent lung dysfunction and pleural disease requiring drainage procedures.

Intestinal Flukes

The large intestinal fluke, *Fasciolopsis buski*, is a common parasite of pigs and humans in eastern and southern Asia. Eggs shed in stools hatch in fresh water, followed by infection of snails, and release of cercariae that encyst on aquatic plants. Humans are infected by eating uncooked plants, including water chestnuts, bamboo shoots, and watercress. Adult flukes mature in about 3 months and live in the small intestine attached to the mucosa, leading to local inflammation and ulceration. Other intestinal flukes that cause similar syndromes include *Heterophyes* (North Africa and Turkey) and *Metagonimus* (East Asia) species; these species are transmitted by undercooked freshwater fish.

Infections with intestinal flukes are often asymptomatic, although eosinophilia may be marked. In symptomatic cases, after an incubation period of 1–2 months, manifestations include epigastric pain and diarrhea. Other gastrointestinal symptoms, ileus, edema, and ascites may be seen uncommonly. Diagnosis is based on identification of characteristic eggs or adult flukes in the stool. In contrast to other fluke infections, illness more than 6 months after travel in an endemic area is unlikely. The drug of choice is praziquantel, 25 mg/kg orally as a single dose. Alternative therapies are triclabendazole and niclosamide (for most species).

Cestode Infections

The four major tapeworms that cause noninvasive infections in humans are the beef tapeworm *Taenia saginata*, the pork tapeworm *Taenia solium*, the fish tapeworm *Diphyllobothrium latum*, each of which can reach many meters in length, and the dwarf tapeworm *Hymenolepis nana*. *Taenia* and *Hymenolepis* species are broadly distributed, especially in the tropics; *D latum* is most prevalent in temperate regions. Other tapeworms that can cause noninvasive human disease include the rodent tapeworm *Hymenolepis diminuta*, the dog tapeworm *Dipylidium caninum*, and other *Taenia* and *Diphyllobothrium* species. Invasive tapeworm infections, including *T solium* (when infective eggs, rather than cysticerci are ingested) and *Echinococcus* species, will be discussed separately (see illustration); (see illustration).

Noninvasive Tapeworm Infections

Beef Tapeworm

Infection is most common in cattle breeding areas. Humans are the definitive host. Gravid segments of *T saginata* are passed in human feces to soil, where they are ingested by grazing animals, especially cattle. The eggs then hatch to release embryos that encyst in muscle as cysticerci. Humans are infected by eating raw or undercooked infected beef. Most individuals infected with *T saginata* are asymptomatic, but abdominal pain and other gastrointestinal symptoms may be present. Eosinophilia is common. The most common presenting finding is the passage of proglottids in the stool (see illustration).

Fig.

Life cycle of *Taenia saginata* (beef tapeworm). A human ingests undercooked beef with infective cysticerci. ***1–6:*** Tapeworm cysts are digested free in the duodenum (1) and a scolex evaginates and attaches to the mucosal surface, where it develops into an adult worm in about 3 months. The scolex, with its four suckers and no crown of hooks (2), serves as a hold-fast organ. Terminal gravid segments (3) show typical numerous (over 12) main branches of the uterus; these egg-filled segments break off and pass out in the stool (4), whence they may crawl a short distance, adhere to grass, and be eaten by cattle. The eggs (5) are digested free, hatch to release oncospheres that penetrate the gut wall, and are carried by the bloodstream to the striated muscles. There the oncosphere changes to a rice grain-sized vesicle with a single inverted scolex and a germinative neck (6). After being ingested with undercooked beef, the cysticercus is digested free (1), everts the head and neck, attaches the scolex by its four muscular suckers, and in about 3 months forms the adult worm, a chain of 1500–2000 segments, the strobila, about 5–9 m long. (Reproduced, with permission, from Goldsmith R, Heyneman D [editors]: *Tropical Medicine and Parasitology*. Originally published by Appleton & Lange. Copyright © 1989 by The McGraw-Hill Companies, Inc.)

Pork Tapeworm

T solium is transmitted to pigs that ingest human feces. Humans can be either the definitive host (after consuming undercooked pork, leading to tapeworm infection) or the intermediate host (after consuming food contaminated with human feces containing *T solium* eggs, leading to cysticercosis, which is discussed under invasive tapeworm infections). As with the beef tapeworm, infection with *T solium* adult worms is generally asymptomatic, but gastrointestinal symptoms may occur. Infection is generally recognized after passage of proglottids. Autoinfection with eggs can progress to cysticercosis (see illustration).

Fig.

Life cycle of *Taenia solium* (pork tapeworm). Ingestion of undercooked or raw pork results in release of cysticerci digested from the meat in the human duodenum. ***1–4:*** The scolex everts (1), develops into an adult worm in 2 months, and daily sheds egg-filled segments (2) that are passed with feces. Pigs ingest feces with the gravid segments. The eggs (3) hatch in the gut. Oncospheres penetrate the intestine and pass by the bloodstream to the tissues, in which the cysticerci develop. In (4) is shown an individual cysticercus with its bladder and inverted scolex with a double row of rostellar hooks. Humans who eat food contaminated with human feces may ingest eggs and develop cerebral cysticercosis. (Reproduced, with permission, from Goldsmith R, Heyneman D [editors]: *Tropical Medicine and Parasitology*. Originally published by Appleton & Lange. Copyright © 1989 by The McGraw-Hill Companies, Inc.)

Fish Tapeworm

Infection with *D latum* follows ingestion of undercooked freshwater fish, most commonly in temperate regions. Eggs from human feces are taken up by crustaceans, these are eaten by fish, which are then infectious to humans. Infection with multiple worms over many years can occur. Infections are most commonly asymptomatic, but nonspecific gastrointestinal symptoms, including diarrhea, may occur. Diagnosis usually follows passage of proglottids. Prolonged heavy infection can lead to megaloblastic anemia and neuropathy from vitamin B12 deficiency, which is due to infection-induced dissociation of the vitamin from intrinsic factor and to utilization of the vitamin by worms (see illustration).

Fig.

Life cycle of *Diphyllobothrium latum* (broad fish tapeworm). Ingestion of raw or inadequately cooked fish containing plerocercoid larvae is followed by development of a tapeworm in the small bowel and passage of feces containing operculated eggs. Eggs deposited in a freshwater pond or lake hatch and infect the first intermediate host, a copepod (water flea). The infected copepod conveys the early larval form to a small fish, which can in turn infect a number of piscivorous fish until a human or other piscivorous mammal feeds on the larger fish and acquires the infection. ***1–6:*** The scolex (1) of an adult worm attaches by sucking grooves to the wall of the small intestine. Mature segments (2) deposit eggs in the gut lumen that are passed in stool (3). Eggs that reach a freshwater pond hatch after a period of development, releasing the ciliated coracidium (4), which develops in the first intermediate (copepod) host into the procercoid (5). Fish—often minnows—feed on the copepods and digest the procercoids free. The procercoids penetrate the gut, pass to the fish musculature, and mature into a nonencysted plerocercoid (6) capable of passing from the gut of one transport fish host to the flesh of a larger piscivorous host. The final transfer occurs when a human or other piscivorous mammal feeds on the infected fish and digests the plerocercoid free. The young worm attaches by its scolex and grows into an adult tapeworm, often 8 m or more in length and up to 2 cm in breadth. (Reproduced, with permission, from Goldsmith R, Heyneman D [editors]: *Tropical Medicine and Parasitology*. Originally published by Appleton & Lange. Copyright © 1989 by The McGraw-Hill Companies, Inc.)

Dwarf Tapeworm

H nana is the only tapeworm that can be transmitted between humans. Infections are common in warm areas, especially with poor hygiene and institutionalized populations. Infection follows ingestion of food contaminated with human feces. Eggs hatch in the intestines, where oncospheres penetrate the mucosa, encyst as cysticercoid larvae, and then rupture after about 4 days to release adult worms. Autoinfection can lead to amplification of infection. Infection with *H nana*, the related rodent tapeworm *H diminuta*, or the dog tapeworm

D caninum can also follow accidental ingestion of infected insects. *H nana* are dwarf in size relative to other tapeworms but can reach 5 cm in length. Heavy infection is common, especially in children, and can be accompanied by abdominal discomfort, anorexia, and diarrhea.

Laboratory Findings

Diagnosis is usually made based on the identification of characteristic eggs or proglottids in stool. Egg release may be irregular, so examination of multiple specimens or concentration techniques may be needed (see illustration); (see illustration).

Treatment

The treatment of choice for noninvasive tapeworm infections is praziquantel. A single dose of praziquantel (5–10 mg/kg orally) is highly effective, except for *H nana,* for which the dosage is 25 mg/kg. Treatment of *H nana* is more difficult, as the drug is not effective against maturing cysts. Therefore, with heavy infections with this parasite a repeat treatment after 1 week, and screening after therapy to document cure are appropriate. Therapy can be accompanied by headache, malaise, dizziness, abdominal pain, and nausea.

The alternative therapy for these infections is niclosamide. A single dose of niclosamide (2 g chewed) is effective against *D latum, Taenia,* and *D caninum* infections. For *H nana,* therapy is continued daily for 1 week. Niclosamide may cause nausea, malaise, and abdominal pain.

Invasive Cestode Infections

Cysticercosis

Essentials of Diagnosis

- Exposure to *T solium* through fecal contamination of food.
- Seizures, headache, and other findings of a focal CNS lesion.
- Brain imaging shows cysts; positive serologic tests.

General Considerations

Cysticercosis is due to tissue infection with cysts of *T solium* that develop after humans ingest food contaminated with eggs from human feces, thus acting as an intermediate host for the parasite. Prevalence is high where the parasite is endemic, in particular Mexico, Central and South America, the Philippines, and Southeast Asia. An estimated 20 million persons are infected with cysticerci yearly, leading to about 400,000 persons with neurologic symptoms and 50,000 deaths. Antibody prevalence rates up to 10% are recognized in some endemic areas, and the infection is one of the most important causes of seizures in the developing world and in immigrants to the United States from endemic countries.

Clinical Findings

Symptoms and Signs

Neurocysticercosis can cause intracerebral, subarachnoid, and spinal cord lesions and intraventricular cysts. Single or multiple lesions may be present. Lesions may persist for years before symptoms develop, generally due to local inflammation or ventricular obstruction. Presenting symptoms include seizures, focal neurologic deficits, altered cognition, and psychiatric disease. Symptoms develop more quickly with intraventricular cysts, with findings of hydrocephalus and meningeal irritation, including severe headache, vomiting, papilledema, and visual loss. A particularly aggressive form of the disease, racemose cysticercosis, involves proliferation of cysts at the base of the brain, leading to alterations of consciousness and death. Spinal cord lesions can present with progressive focal findings.

Cysticercosis of other organ systems is usually clinically benign. Involvement of muscles can uncommonly cause discomfort and is identified by radiographs of muscle showing multiple calcified lesions. Subcutaneous involvement presents with multiple painless palpable skin lesions. Involvement of the eyes can present with ptosis due to extraocular muscle involvement or intraocular abnormalities.

Laboratory Findings

CSF examination may show lymphocytic or eosinophilic pleocytosis, decreased glucose, and elevated protein. Serologic tests can indicate prior exposure to *T solium*, but both sensitivity and specificity are limited.

Imaging

The diagnosis of neurocysticercosis can be difficult. With neuroimaging by CT or MRI, multiple parenchymal cysts are most typically seen. Parenchymal calcification is also common. Ventricular cysts may be difficult to visualize, with MRI offering better sensitivity than CT (see CT scan); (see CT scan).

Copyright © 1989 by The McGraw-Hill Companies, Inc.)

Treatment

The medical management of neurocysticercosis is controversial, as the benefits of cyst clearance must be weighed against potential harm of an inflammatory response to dying worms. Antihelminthic therapy hastens radiologic improvement in parenchymal cysticercosis. However, some randomized trials have shown that corticosteroids alone are as effective as specific therapy plus corticosteroids for controlling seizures, and some reports have shown exacerbation of disease after antihelminthic therapy. Considering active lesions, disease with a high likelihood of progression, such as intraventricular cysts, may benefit from therapy. At the other end of the spectrum, inactive calcified lesions probably do not benefit from therapy. Overall, it remains difficult to determine when treatment is indicated. When treatment is deemed appropriate, standard therapy consists of albendazole (10–15 mg/kg/d orally for 8 days) or praziquantel (50 mg/kg/d orally for 15–30 days). Albendazole is probably preferred, since it has shown better efficacy in some comparisons and since corticosteroids appear to lower circulating praziquantel levels but increase albendazole levels. Increasing the dosage of albendazole to 30 mg/kg/d orally may improve outcomes. Corticosteroids are usually administered concurrently but dosing is not standardized. Patients should be observed for evidence of localized inflammatory responses. Anticonvulsant therapy is provided if needed, and shunting is performed if required for elevated intracranial pressure. Surgical removal of cysts may be helpful for some difficult cases of neurocysticercosis and for symptomatic non-neurologic disease.
